## THE MANIC DEPRESSIVE PSYCHOSIS AND SOME OF ITS ETIOLOGICAL AND PATHOLOGICAL PHASES.

BY WALTER D. BERRY, M.D.,

CLINICAL DIRECTOR AND PATHOLOGIST, STATE HOSPITAL FOR THE INSANE, WATERBURY, VT.; PROFESSOR OF MENTAL DISEASES, UNIVERSITY OF VERMONT MEDICAL COLLEGE.

BEFORE narrating the history of a case of manic depressive insanity, it may not be amiss for me to review certain points relative to the statistics, etiology, and pathology of this disease.

From the large number of statistics, it has been learned that about 15 per cent. of admissions to insane hospitals are in reality none other than the class known as the manic depressive state. From these statistics we also learn that men do not have the disease as often as do women, and of the etiological features, hereditary defectiveness plays a most important rôle, 70 to 80 per cent. of all cases having an hereditary legacy handed down to them through the avenues of mental bent toward this disease. Previous to the exact breaking down, these patients display certain peculiarities, such as being abnormally bright or showing a tendency toward eccentricity or over-piety, but in quite a different manner to that of dementia præcox.

As to physical stigmata, they may be present, although such symptoms do not seem to be pathognomonic of the disease in any way. Individual attacks usually occur quite independent of external causes, with the exception of the first breakdown, which, in the vast majority of instances, does seem to be connected in some way with such external stimuli. Of these external stimuli or predisposing factors, alcoholic excess and parturition seem to be extremely caustive, and in other cases mental shock or trauma and improper nutrition during acute disease appear to have considerable bearing in bringing on attacks.

In by far the larger number of cases the first attack usually begins about the twenty-fifth year, and in somewhat less than 10 per cent. about the fortieth year; in these two periods the female sex predominates.

In taking up the distinctive meaning of the term manic depressive psychosis, it is now applied to that form of mental disease which is distinctly recurrent as definite forms appearing at varied intervals throughout the psychic life of the individual and, as has been said previously, has hereditary defectiveness as the most prominent factor. By far the greater number of the cases usually diagnosed delirious mania, simple mania, periodic mania, simple and recurrent melancholia, and circular types, really belong to this group of mental diseases. When these cases are reviewed according to the old conception they present diagnostic difficulties on account of the too frequent occurrence of conflicting symptoms, which would be in keeping with a diagnosis according to the older conception.

It also sometimes occurs that a typical picture of circular insanity may be mistaken for this psychosis, and therefore the diagnostic picture be marred by the appearance of distinctly maniacal or melancholic attacks. One has only to review any series of cases of periodic mania or melancholia, noting these varying features, to be forced to conclude that on account of such inharmonious manifestations they are not accidental but in reality are certain phases within one distinct symptom-complex.

On account of the frequent recurrence of the fundamental symptoms in all of the different attacks, the oneness of their course and result in the occasional relation with different forms of the disease, wherein one form may run over gradually into another, these conditions have gradually led alienists to the conclusion that manic depressive insanity appears in at least one of three types, viz., the maniacal, the depressed, and the mixed type. The maniacal form is usually characterized by great motor and psychomotor restlessness, frequent flight of ideas, word salads, formal associations, distractibility, inharmonious emotional attitude, varied delusions, hallucinations, pressure of activity, and usually very little clouding of the consciousness. On the other hand the depressed form presents, instead of psychomotor restlessness, psychomotor retardation and a distinctly depressed emotional sphere with abscence of spontaneous activity. Instead of the flight of ideas there is a dearth of ideas, the prominent delusions and hallucinations are of such a character as to be in keeping with the resultant emotional attitude, and a clouding of the consciousness is usually present. The mixed form, as the word implies, is simply a combination of the two previous types, the characteristics of which I have outlined. By such a conception of the case, it is possible to make a diagnosis immediately at the onset of the disease without having to wait for the next attack, as was thought several years ago by prominent alienists.

In regard to the pathology of this psychosis, no characteristic anatomical or pathological changes worthy of note have yet been found. As I have said before in speaking of the etiology of this affection, the pathology necessarily rests upon a neuropathic basis, and this, in a great majority, on hereditary defectiveness. The theory presented sometime ago by Adolph Meyer, explaining the disease as due to a trophic vascular disturbance has already been proved improbable. The theory advanced by Meynert, that the attacks were due to an accelerated pulse of great intensity, and usually with hyperæmia of the extremities, inferred that such a state of congestion also was present in the brain; however this may be true of the maniacal state, the theory does not suit the depressed type, for in this type we have no such vascular or arterial disturbance, the hands and feet being cold and the face pinched and drawn. The theory also would not fit the mixed type.

The longer I am associated with the study of such types of mental disorder, I am more than ever

convinced of the effect of an hereditary *anlage*, and a neuropathic constitution. In order to give some idea of the nature of such cases as they are admitted to the hospital, I will report a case which has recently come under my observation:

April 29, 1903. A woman twenty-nine years of age, with hereditary history of psychosis in the paternal grandfather, grandmother, grandaunt, and two granduncles, and father. The sister is now in this hospital. Maternal heredity is denied by the mother, but consanguinity asserted by neighbors. The anamnesis of the disease is negative in character until the year 1894, when patient is said to have had a slight fall, after which she became unconscious for "a few minutes"—no apparent sequelæ were noted until nineteen days afterward, when she became suddenly insane. She recovered after five months (character of attack unknown). She was always a quiet, tractable girl, strong physically; was married and had one child nine months old at time of the second attack, September, 1898. At the onset she was depressed, worried, and at times confused; after a few days began to talk loudly on awakening in the night, answering voices and "reacting to strange delusions."

Admitted here September 21, 1898, on following physician's certificate: "*Facts observed:* Violent mania, delusions, foul language, attempt of violence upon herself and members of the family. *Facts learned:* Same as stated above."

When brought into hospital office she was wearing a camisole, and threw herself on the floor, refusing to get up; she reacted to auditory hallucinations, also delusions of persecution, saying she was going to be killed, her body cut into pieces and burned; also wove considerable religion into talk. After being taken to the ward she pounded her head, ran about, threw herself on the floor, crying and shrieking. From then until removed from the institution, March 15, 1899, she was alternately excited and depressed, but suicidal in either state—was restrained to bed part of the time—at times violent, striking and resisting nurses. She was emotional, laughing and crying alternately, distractable, irritable, and sullen most of the time—refusing to speak part of the time—practising masturbation on herself and other patients—occasionally smearing room with fæces; somatic delusions were constant—thinking she had no right lung and was losing the left. She was taken from hospital against advice of the staff, and after a time improved so that she got along at home until June 2, 1901, when she was readmitted. She had been violent about a week, but for five weeks previous had been nervous, depressed, emotional, had insomnia and worried for fear of another attack—was maniacal at times—had no fixed delusions—visual hallucinations were admitted, but auditory ones were denied. She had menstruated every two weeks and as the attack occurred was menstruating. Physician's certificate states:—Patient said: "On one occasion threatened to throw herself out of the window of her chamber, said that she saw strange objects and persons in her room, that her friends and neighbors tormented her, that she would not take food because it was poisoned, that she sees and converses with diseased friends, and much more of the same character. *Facts learned:* She sleeps but little, is violent, noisy, prays and sings in a violent manner, attacks members of family violently and refuses to be restrained to prevent her from doing herself or others violence. *Appearance and manner:* excited at times and at others quiet and refuses to speak at all. *Other facts:* She has had two former attacks lasting about six months, in 1895 and 1898 respectively, and was during the latter attack confined in the asylum at Waterbury."

When taken to ward she kicked the doors and walls, talking loudly and irrelevantly—rhyming at times—"I'll smash that door ,damn this floor, Jennie Blood, a precious bud"—said she had "had a great deal of trouble, was in total darkness, without any heaven or God." She was resistive, but after being in the ward a short time became quiet, was quite stupid, but would suddenly spring up, throw herself around, cry, scream, and try to commit suicide. She was well oriented, had partial insight, memory good for recent events; had delusions of poisoning, and auditory hallucinations. She remained in this condition until about August 15, varying between stuporous and excited conditions, sitting with eyes downcast for hours at a time refusing to speak, then having maniacal outbursts, rhyming, with flight of ideas, word salad ("temperance, geography, Mary, Grace, dead, no truth"), also desultoriness ("yes, sir; no, sir; slow, sir; now, sir; white coffin, sir; rough on rats, sir; dead, sir; right, sir"), spelling words, then repeating backwards. The excited period usually lasted about fifteen minutes, very suicidal—after August 15 she improved, and was taken home in October, but returned December, 1901, on following certificate:

"*Patient said:* That she contemplates suicide and continually is designing ways and means for its accomplishment—that she has been deterred from it only by means or because of restraint—that she sees moving objects, particularly at night—that "she hears voices whispering names of persons to her—on one occasion commanding her or suggesting that she jump into the cistern—states that on one occasion she had thought it best to put her young son out of the way, to save him trouble, etc. *Patient did:* She appeared very melancholy—walked back and forth, wringing her hands and apparently in great mental distress. *Appearance and manner:* Quiet, during this examination, but she is talkative and unable to apply her mind or hands to any duty. *Other facts:* She has been twice before committed to the asylum—on both occasions, at times very violent and destructive."

Was quite suicidal, feeling depressed because she had to return to the hospital; had good insight, said if she could not recover she had better be dead; was not excitable, had auditory hallucinations—"a voice said if you try to do better you can; there is some way you can do better"—marked introspection, trying to control impulses and very depressed when unable to do so. She was quiet after admission, said she had no hallucinations after coming to hospital, and after a few weeks appeared to regain her normal condition, remaining in this state until January 10, 1902, when she had a stuporous attack lasting about one hour, during which she refused to speak. There was conjugate deviation to the left, the jaws working convulsively; there was no paralysis, and the woman was able to move all parts of the body and limbs voluntarily. From then until September, 1902, she was generally in a stuporous condition, with maniacal outbursts and suicidal attempts. When excited she was resistive, violent, noisy, talking rapidly, barking, crowing, mewing, bleating, but always well oriented; had good insight, delusions of self-accusation, reacting to auditory hallucinations by standing on her head and jumping about the ward. When depressed she sat with downcast eyes, refusing to speak. She was apparently in a normal condition for about a month, when, on October 28, 1902, the present attack came on with symptoms similar to the others. She is now quite depressed; her temperature is about normal.

*Physically.*—July 15, 1901. Linea albacantia on abdomen, left lobule of ear larger than right, high and narrow palate, reflexes somewhat diminished, slight mitral regurgitation, slight retroversion of uterus, several urethral caruncles, ovaries somewhat tender.

*Uranalysis.*—June 17, 1901, excess of chlorides, phosphates normal, few urates and phosphates. December 7, 1901, diminished phosphates.

*Etiology.* Heredity
Trauma (?)
Pelvic abnormalities (?)

Paternal:
- Grandfather insane.
- Grandmother insane.
- Grandaunt insane.
- Two granduncles insane.
- Father insane.
- Aunt insane after injury to head.
- Two uncles insane.

Maternal: Consanguinity.
Sister in hospital (dementia præcox).

*Duration.*—First attack five months; second attack six months, under observation; third attack seven months, under observation; fourth attack, nine months, under observation; fifth attack began October, 1902.

*Treatment.*—Hospital routine; restraint from self-injury; special diet; hot packs for excitement with good result; syr. hypophos. co. for tonic; exercise outdoors when consistent; hypnotic for persistent motor and psychomotor restlessness with insomnia.

*Diagnosis.—Manic depressive insanity* (mixed form), fifth attack, characterized by a sudden onset; alternating periods of stupor and excitement, either of which predominates at varied intervals; continuous phases of depression, self-accusation, motor and psychomotor restlessness as well as psychic retardation, mutism, refusal of food and somatic delusions during the apices of maniacal phases presented the characteristic symptoms, such as rhyming, word salad, pressure of activity, inharmonious emotional sphere, together with considerable destructiveness. The patient showed no disorientation as to place, persons or time, and had considerable insight even during excitement.

Dementia præcox was excluded immediately upon learning of the anamnesis, and was further ruled out on account of the absence of the usual symptoms complex displayed while in the hospital.

*Prognosis.*—Will probably recover from this attack, but will undoubtedly have subsequent attacks of like character, recovering from each with a shorter period of lucidity between attacks, so that finally there will be considerable amount of dementia mixed in with a more or less continuous maniacal stupor.

In connection with the foregoing summary and notes, I wish to acknowledge the valued aid of my co-worker Dr. Upton, who was intimately associated with the care and treatment of the case.

As we look at the subject of heredity, which is not by any means an uncommon feature, in connection with these and many other cases, we at once realize or give more or less theoretical speculations concerning that peculiar quality or property of organisms which enables them to transmit their essential characteristics to their decendants. Its action appears to be universal and covers all forms of life, whether vegetable, animal or human. Its roots reach down into the very element of all living structures, and appears to be one of the fundamental essentials of life itself. It passes beyond the bounds of healthy functions into morbid conditions of both mind and body. Stearns says "the *modus operandi* of this marvelous process—this universal biological law—has always hitherto remained, and perhaps still does remain, a sealed book. By what process or method this influence may extend over several generations, manifesting itself in some particular form or disease in one or more persons, and not in others; affecting one member of the family and not another of the same family; how a peculiar character, such as the color of an eye, the hair, the skin, the size and form of the mouth, the teeth, the hand, the foot; the mental and moral characteristics, and even peculiar movements of hands and body, may all appear in one or more individuals in a generation and in no others, these physiological processes have remained a mystery, while observers have been obliged to occupy themselves with the study merely of certain phenomena and characters in organisms, which we say are due to hereditary influences."

Within comparatively few years, however, the study of this subject has received a new impetus. It now relates not so much to the character of the results, as it does to the intricate and delicate arrangements which nature has provided for securing these far-reaching results. This part of the subject, however, is too technical to be introduced into a treatise of this kind. My present purpose, in presenting this subject, has to do with another phase of heredity, viz., that relating to mental disorders.

In a condition of ordinary health the thought process occurs automatically, except during the hours of sleep, and even then it may take place in what we call dreams, the character of which the person has a sort of subconscious realization. Its activity, however, during dreams is not subject to the will of the individual. During our waking hours, the impressions received upon the end organs of the five senses, and from the revival of the stored-up experiences of the past, give rise to mental activities which express themselves in the form of speech or motion, if they are presented in outward manifestations at all. But it is frequently the case that these thought activities do not pass from the brain and discharge themselves in any form of outward manifestation. They can be arrested and examined by the personality; be approved or disapproved; be analyzed or modified and formed into new combinations which commend themselves more or less fully to the personality and thus become opinions and beliefs; or they can be disapproved and rejected.

Such a belief is the physiological action of that portion of the brain, the function of which relates to sensation, perception and thought when it is in a state of normal and conscious activity. But when by reason of unfavorable influences and experiences, such as over-exertions, long-continued anxiety, uncertainty and worry, ill health; or from the effect of poisons acting upon its delicate structure, such as foul air, alcohol, opium, and the products of disorganized tissues of the system which have been eliminated from it; or, again, from the influence of unfavorable inheritances; these physiological activities of the brain become deranged and changed in character so that the actions and reactions are no longer normal, the effects are manifested in states of mind which we call insanity. In other words, that condition of mind which we term insanity, arises from or consists in the morbid and disordered activities of certain portions of the brain and general nervous system.

Now, when the brain has once become deranged in its normal action, or has passed through a storm of excitement in connection with an attack of mania or the profoundly depressed condition usually seen in melancholia and other forms of insanity, its cell structures do not readily return to a state of healthy function. On the contrary, there is likely to remain for a long time a supersensitive condition of it, and more or less probability that from the experiences of the past in uncertainty, trouble

and disappointment, there will again occur a disorder of mental function. Habit of action in the normal condition becomes a sort of second nature to most persons—much more does a habit of action which has been established in a disordered state of the mind tend to become permanent or liable to return again if recovered from. It is this very thing, *i. e.* the acquired or inherited tendency of the brain toward unstable and morbid action, that is more likely to be transmitted than almost any other morbid condition.

I must also add that in this condition it is not necessary that the peculiar condition in the parent should be developed into actual insanity to insure its doing so in the offspring. It is not infrequently observed that qualities of mental action in one parent which have been regarded as nothing more than eccentricities or peculiarities—sometimes developing in periods of degression and morbid irritability—when crossed with certain characteristics in the other parent, the nature of which may not be known—these not infrequently develop into one of actual insanity in succeeding generations.

Again—a tendency toward some one diathesis or form of disease in one generation may assume in a succeeding generation a very different form of disease or diathesis. For instance, a consumptive or rheumatic parent may have children who are quite free from tendencies toward that particular form of disease, and yet inherit a brain of such an unstable organization that it has attacks of insanity; or, *vice versa*, a patient who has been affected with insanity may have children who have scrofulous or consumptive diathesis.

On the other hand, if one of the parents has a vigorous constitution and a nervous system unusually robust, and is endowed with a tendency to longevity, these qualities may prove sufficiently potent to overbalance any weakness and tendencies toward disease in the other parent and the offspring may be healthy, though in some degree affected by the infirmities of the weaker parent. Some persons and families seem to be endowed with unusual ability in transmitting healthy characteristics of race and nationality, and this may prove an important factor toward eliminating tendencies to disease on the other side of the house. In these two characteristics or qualities, which we may assume exist to some extent in all healthy persons, there is contained a power of incalculable value to the human race—indeed, one essential to its continued existence—that is, a tendency on one side to overcome weakness and disease on the other which might otherwise continue to increase, especially under the influence of unfavorable environments.

From these considerations, the danger from consanguinous marriages becomes apparent. Numerous tables of statistics present abundant evidence going to show that intermarriages result very disastrously. The children are not infrequently deaf mutes or idiots, scrofulous, phthisical, insane, or otherwise deficient in mind and body.

In this way we see how much more danger there is that a morbid heredity will increase. Like tends to beget like, and if two persons with a tendency toward the same constitutional diathesis or disease are unfortunate enough to marry, the tendency toward this disease becomes double in the offspring. In case only one parent has a morbid tendency, the influence of the other, if healthy and strong, may be sufficient to overcome and eliminate it in the offspring.

You all know that persons and animals of the same family necessarily inherit the same tendencies toward health and disease to a greater or lesser extent, according to the degree of consanguinity. Persons with no blood relationship are much less likely to have like tendencies. Indeed, they are likely to have characteristics which would have a counteracting influence upon such unfavorable tendencies in others.

We readily, therefore, perceive the danger of unfavorable results from marriages among blood relations, not because of the mere fact of relationship, but because of the probability of increasing tendency toward any special form of diseases which may exist in both parties.

The question arises whether a person who has passed through an attack of insanity should contract marriage. It would not be easy to formulate a rule which would cover all cases and never be set aside; but in view of the fact that when one has been insane he will ever afterward be in great danger of another attack, it is of the greatest importance that all parties concerned should have a full understanding of the case. The practice more generally pursued of keeping the fact that a person has had such an experience, especially when that person is a woman, cannot be too strongly censured. If, after a full explanation, and the other party has consulted friends and obtained a professional opinion, he or she chooses to go forward and consummate marriage, it is in some respects a matter of his or her own concern. *However, the infliction of the State with children having such an inheritance, is criminal.*

If, however, the female is past the period of childbearing, the objections to marriage, so far as they relate to children, would, of course, be *nil*. But when there is a reason to anticipate progeny, persons contracting marriage assume a responsibility which we, as physicians, will not be willing to assume. In case the insanity has been the development of inheritance and has existed in either immediate or remote direct ancestors, the risk becomes even greater. If, on the other hand, the attack can be attributed to some accidental experience or physical disorder, and the other party has a vigorous constitution and good inheritance, the danger becomes less. In such cases there exists a reasonable probability that the stronger and more stable qualities of nerve tissue will triumph over and eliminate the weaker ones.

In taking up further the pathogeny of this affection, I am at present conducting tentative inquiries concerning the causative factors in bringing on the different attacks. Leucocytosis, anæmia, and alternate decrease and increase of weight seem to have some connection with this state. Therefore until a sufficient number of such cases have had skilled "blood-counts" made and an hæmoglobin curve averaged, I am unable to give an exact statement concerning the relation of those factors.

If, however, I have succeeded in enlightening any of my professional brethren in regard to this psychosis and its relation to the mental and physical condition, together with speculations as to its pathogenesis, I will have accomplished the object of this effort.

---

**The Danger of Being Alive.**—Drink water and get typhoid fever. Drink milk and get tuberculosis. Drink whiskey and get the jim-jams. Eat soup and get Bright's disease. Eat meat and encourage apoplexy. Eat oysters and acquire toxæmia. Eat vegetables and weaken the system. Eat dessert and take to paresis. Smoke cigarettes and die early. Smoke cigars and get catarrh. Drink coffee and obtain nervous prostration. Drink wine and get the gout. In order to be entirely healthy one must eat nothing, drink nothing, smoke nothing, and even before breathing one should make sure that the air has been properly sterilized.—*South-Western World.*

## CAUSES, CONSEQUENCES, AND CARE OF THE INJURIES TO THE PARTURIENT CANAL.*

By BENSON M. FELDMAN, M.D.,
ATTENDING GYNECOLOGIST TO THE SYDENHAM HOSPITAL DISPENSARY, NEW YORK.

It is no exaggeration when I claim that a large portion of the work of the operating gynecologist is but a consequence of, or a sequel to, the inefficiency of the general practitioner in obstetric work.

This paper is based principally on a long personal experience, and if I succeed in convincing the general practitioner that he should feel his responsibility more in cases of obstetrics, and exert every effort to forestall the gynecologist, I shall have accomplished something which will redound to the satisfaction of every physician, who in the triumph of having delivered into this world another human being, will not have to face well-deserved blame subsequently.

I do not care to burden you with a recital of histories, and I cannot include lacerations or ruptures of the uterus above the cervix, as that would make my paper too lengthy for the time allotted.

The varieties and causes of tears in the various portions of the genital tract are many. In the cervix we have the slight unilateral or bilateral lacerations, which occur in primiparæ consequent upon a rapid second stage, when the first stage was of too short a duration properly to encourage or complete dilatation.

The lacerations of the cervix may be multiple, especially as a result of manual or instrumental dilatation or other interference. Cases of annular laceration, in which a complete ring of the cervical margin was torn away by forceps, are on record. Cervical laceration may extend in any direction and any distance upward and outward.

Application of forceps, or even spontaneous delivery, while the patient has a full bladder or rectum, may produce injury. In the hands of the general practitioner undue haste in the forcible dilatation and application of the forceps probably causes the largest number of cervical injuries.

Certain forms of dystocia, among which we may mention disproportionate size of the head and shoulder and breech presentations, are responsible for them.

High and medium forceps applications may produce quite extensive injury to this part of the uterus; the tears sometimes extending into the fornix or the lateral ligaments.

I recently saw one case of medium forceps delivery, the second traction position having been assumed too early, in which the resulting tear extended through the cervix on the left side, the lateral wall of the vagina, and all the neighboring tissue, so that upon introducing the hand, one could feel the external surface of the entire rectum, which had thus been exposed.

Injuries of this nature are due either to unskilful instrumentation or bad judgment. By the latter I mean that, when the dystocia existed, version with the head still above the pelvic brim, or some other procedure would have been more advisable. Insufficient dilatation at the time, of the upper part of the canal and cervix may be the cause of injury.

These severe lacerations extending beyond the vaginal attachments are most frequently the result of pulling out the after-coming head-in breech deliveries, when the cervix is insufficiently dilated, or when it has retracted around the head after the shoulders have escaped. Wedging in of the anterior lip between the os pubis and the child's head may be a factor in the production of the cervical tear.

*Read at a meeting of the Manhattan Clinical Society.

In occiput posterior positions one should always look for cervical lacerations, although this variety is usually not complicated by hemorrhage.

Dr. J. Duncan Emmet has reported a case of double laceration of the cervix and laceration of the anterior and posterior vaginal walls. This was probably produced by forcing a hip through the cervix, when only one leg was delivered. In placenta prævia pulling the hip through too rapidly severely lacerates the cervix. A flexed knee, wedged in one side, if forcibly withdrawn, may produce a severe injury to the cervix.

Among the unavoidable causes are tumors in the lower uterine segment, or protruding through it, and atresia of the os externum and cervical canal, due to inflammatory processes or to the old-fashioned method of cauterizing the cervix and from scar tissues.

The consequences of injuries to the cervix are immediate and remote, both of which place the patient's health and life in jeopardy. Postpartum hemorrhage is a frequent immediate result, sometimes exsanguinating the patient, and it may even prove fatal.

Even with a thoroughly contracted uterus, the cervical laceration may bleed sufficiently to warrant the condition being characterized as an extensive postpartum hemorrhage, on examination the blood being felt trickling along the finger. If this tear extends into the parametrium, there may be bleeding into the peritoneal cavity. Another, and pathologically more important consequence, is the exposure to infection, to which the puerperal woman is liable. It is a question whether the cervical tear is more frequently the point of entrance for infection than are lesions in another part of the canal.

In my experience, more sepsis has developed in cases in which the floor of the pelvis was involved and in complete perineal rupture.

Every practitioner has encountered those well-known results of cervical laceration, such as endometritis, subinvolution, hyperplasia, and the consequent prolapsus. We may get subinvolution without inflammatory changes.

In recent years our best gynecologists have come to recognize cancer of the cervix as one of the remote results of cervical laceration, if the same is not remedied by plastic operation, which also removes the scar tissue. H. J. Boldt, in Keating's work, page 604, with reference to the etiology of uterine cancer, says: "We may consider a long continued cervical catarrh, with erosion and also cervical laceration, causing such pathological changes, as direct etiological factors."

Before proceeding to any consideration of the next portion of the parturient canal, I wish here to impress upon the physician engaged in obstetric work the great importance of making a thorough examination of the canal, after the placenta has been delivered, even if there is no unusual amount of hemorrhage. The aseptic fingers can positively do no harm in the puerperal vagina. I cannot be too emphatic in advising this procedure.

The tears occurring in the fornix and the upper part of the vagina are generally continuous with those of the cervix; yet isolated lacerations of this part of the vagina do occur; especially do the blades of the forceps occasion these rents, if they are not properly applied. They are of considerable importance on account of their proximity to the peritoneum, and thus they lay bare the parametrium to the dangers of infection.

These tears may result in fistulous communications between the bladder and the rectum, in vesico-

vaginal fistulæ, or in tearing away of the vagina from the bladder, which means a vesical prolapsus.

Hedra, in the first volume of the *Medical Register*, says, "Many of the ill results following delivery are due to injuries in the vaginal fornix and the upper part of the parturient canal and are consequently overlooked." They are overlooked because they give rise to no special symptoms.

A rare variety of injury to the anterior vaginal wall is well described by Hedra, in the article just mentioned. "The impacted head, in its further progress, tears loose the upper portion of the anterior vaginal wall from the bladder and from the anterior surface of the cervix, turning it into a loose pouch, which the bladder will have to follow on account of gravity."

The impacted head may do similar damage posteriorly, separating the posterior wall from its adhesions to the surrounding tissue. There may be a longitudinal, oblique, or antero-posterior laceration of one side of the upper vagina, caused by the forcible introduction of the first or second blade of the forceps. A transverse laceration of the posterior wall of the upper vagina may be due to a transverse head position, with contracted pelvis.

Lusk, in his "Science of Midwifery," states: "In contracted pelvis, when the head is embedded in the brim of the pelvis, the overdistended vagina may give way, in which case the laceration occurs in the transverse or oblique direction, and usually upon the posterior wall."

Among other causes are vesical calculi of large size, which may tear into the anterior vaginal wall by becoming impacted during the descent of the child's head, and the presence of unyielding cicatricial tissue from atresia vaginæ, the result of constitutional disease or former injuries.

Dr. F. W. N. Hazelton, in the *Journal of Obstetrics and Gynecology*, February, 1902, reported a case of lacerated vagina, in which a dermoid cyst of the ovary was forced through the posterior vaginal wall by the head of the child. The rent was large enough to admit a strip of iodoform gauze two inches broad and four feet long.

Deep tears posteriorly or laterally in the vagina will, on exposure with a speculum, show small jets of blood, which account for constant bleeding, and they sometimes lay bare a large vein, especially if the patient has piles. Injuries in this particular locality do not necessarily occur or become apparent at the time of delivery. The parts undergo considerable pressure in dystocia, and the resulting necrosis goes on during the puerperal week, at the end of which time it begins to produce characteristic symptoms.

Postpartum pelvic exudates and pelvic abscesses are but septic infections, due to the absorption of the micrococci through the break in the tissues, although they may also occur as secondary to septic endometritis and gonorrhœal infection. Cystocele, rectocele, and atresia are frequent sequelæ.

The pelvic floor is the bane of the accoucheur's life. Not only in difficult labors, but in comparatively mild cases, we are often surprised to find, when the patient first leaves her bed, or at the usual postpartum examination six weeks later, that there is quite a relaxation of the vaginal outlet—in fact, a sinking of all the supporting parts. One should always think of the possibilities of this condition when making an exploratory examination for injuries immediately after delivery, and not be surprised at finding how thin the tissues are between the vagina and the rectum. On this examination a postvaginal injury to the muscular group can be demonstrated, which is usually ascribed to overstrain or distension at labor. We find no surface evidences of the lesion, unless it results in the formation of hæmatoma, which betrays itself by the postpartum vaginal pain it produces.

The later consequences of these relaxations can easily be recognized, and are of common occurrence. This condition of relaxed vaginal outlet is principally found in elderly primiparæ, over thirty-five years of age. In this class of patients I expect this condition, although the examination did not divulge it, if, during their childbed week they complain of pain in the region of the sacrum.

Some authorities estimate the frequency of lacerations of the pelvic floor and perineum at 35 per cent. of all cases, in first labors and 10 per cent. in subsequent labors. We have several degrees and varieties.

The injury may involve only the posterior commissure of the vulva and about one inch of the vagina, tearing through the congested and œdematous mucous membrane, or it may extend almost to the sphincter ani, involving fascia, fibers of the sphincter vaginæ, transversus perinei and levator muscles, and possibly even the sphincter ani muscle and the skin, and also from one to two or more inches of the rectum. This last-mentioned variety is the complete perineal rupture.

Many cases of central perineal rupture are recorded. Dr. Zangenmeister, in the *Centralblatt für Gynäkologie*, 1901, reports two forms of central rupture which are very interesting. The first patient was a young primipara: "At the time of the crowning of the occiput the vulva became more and more drawn to the front, the perineum became thinner and thinner —before an incision could be made, the perineum tore in the central part; immediately another tear extended forward to the frenum and to the anus." The second patient was also a primiparæ: "As the head crowned, it pushed the whole vulva forward, the perineum became greatly stretched and the anterior margin of the vulva came close to the pubis. A crescentic tear appeared in front of the anus, followed immediately by a tear of the perineum anteriorly, through the frenum. This case exhibited, as a result, an ordinary tear of the perineum, and between it and the anus was a transverse tear, extending in front of the latter."

In my last case of central rupture, the child forced its way through the rent, continuing the tear anteriorly toward the fourchette. The mode of tearing in perineal lacerations varies with the causes operating. They usually proceed from above downward, or from within outward. We rarely find an external laceration without a coexisting internal tear, yet how often in our obstetric experience do we discover a most serious internal laceration without any external manifestations.

In primiparæ and in forceps cases, there is no doubt that the head of the fœtus is the only cause of perineal injury, and not the shoulders.

Dr. Herman, at a meeting of the Obstetrical Society of London in 1901, described an interesting perineal rent, in the case of flat pelvis, in which, after the head had been extracted, the child's hand protruded through the anus; the uninjured perineum being between the anus and the head—the next pain drove down the shoulder, tearing through the rectovaginal septum, from above downward. In breech presentations, the introduction of the hand to relieve an arm, may extend a light perineal tear.

A few other causes for perineal injury are malpositions and malpresentations, scarred or rigid perineum, flat sacrum, a narrow pubic arch causing over-distention, and some reflex impulse causing a sudden violent uterine contraction which forces

the entire child and instruments out with one pain.

In a case of the last variety, in which the contraction or labor pain occurred just as the blades of the forceps were being locked, a complete perineal tear resulted, extending up two and a half inches on the rectal wall.

Perineal injuries may give extensive bleeding with sloughing of tissue, may afford an entrance for infection, and later, if they are not properly repaired, may entail such consequences as prolapsus of all the pelvic organs. The almost fatal hemorrhage which may occur, with injury to the clitoris or vestibule, is, fortunately, very rare.

Prophylactic measures should be begun during the latter months of pregnancy. Hemorrhoids should be treated during pregnancy, especially in primiparæ over thirty years of age. Atresia vaginæ needs gradual dilatation. Bands of mucous membrane extending across the lumen of the vagina should be cut. During labor, especially when the accoucheur is pressed for time, the temptation to hurry matters is very strong, and it often leads him into making matters more difficult.

The amniotic sac should not be opened until dilatation is complete, although in vertex cases, if the position is not faulty, and there is no apparent disproportion between the head and maternal parts, the accoucheur may venture to cut the first stage short, after having satisfied himself as to the dilatability of the os uteri, yet in breech presentation, and still more in footling cases, it is absolutely necessary to prolong the first stage as long as possible, even if the bulging sac comes down to the vulva. The bag of waters must not be broken until the dilatation of the cervix is complete beyond peradventure, as this is the only chance we have of preventing the cervix from contracting around the child's neck, and thus interfering with the delivery of the after-coming head; I will not call it retraction, for the condition must not be confounded with true physiological uterine retraction.

In cases in which the anterior lip of the uterus is wedged in between the pubic bone and head, and acts as an obstacle to the progress of labor, it should be pushed up with the side of the index-finger, in the interval between labor pains, and kept there until the contraction is completed.

Before a resort to forceps, the accoucheur must not fail to have the patient's bladder and rectum empty.

The employment of high forceps, I consider a capital operation, always a dangerous procedure, and it should never be done by the general practitioner, unless he has had considerable experience, for even in expert hands, the destructive results are sometimes unpleasant, although by the use of Tarnier's latest traction forceps we may reduce the degree of injury which may be occasioned.

Version is a wiser procedure, especially if the head is not yet engaged, or even if it is so engaged, but yet movable above the brim of the pelvic inlet.

Before applying medium forceps one should make a thorough examination for diagnostic purposes—the patient being anæsthetized, and the whole hand being introduced if necessary. Having made a diagnosis, the operator should follow the mechanism of labor in that particular position, so that in the extraction he may closely imitate the natural process, never forgetting that a rapid extraction does not signify skill. The grasp of the blades should be occasionally relaxed, thus allowing for rotation, which generally occurs spontaneously.

The alternate descent and recession of the head are the best means of overcoming rigidity, especially if the parts are small and the head is above the moderate size.

Great caution is necessary in the application of forceps in contracted pelves; when the head has been wedged in for some time, before attempting to introduce the blades, one should always examine to see if a laceration does not already exist.

Version should not be undertaken until the dilatability of the cervix and upper part of the vaginal canal has been determined, and even with a dilated cervix there is probability of a tear, if the amniotic fluid has escaped prematurely.

As the head reaches the pelvic floor, the rapidity of its progress should be at the command of the operator, who should use chloroform, certainly in primiparæ, to control the strength and the frequency of the uterine contractions, and thereby the rapidity of the expulsion, as it is just at this time that unforeseen injuries in the rectovaginal septum begin.

As a preventive of laceration, one physician recently advised placing adhesive straps, two inches broad, on the perineal skin, extending from the labium majus on each side to the hip on the opposite side and another transverse strip over the perineum. This cannot be kept in an aseptic condition, nor can it save a perineum, which usually tears as a continuation of the rent started above on the post-vaginal wall.

Dr. Weston has advised the introduction of a deep suture into the perineum, from side to side, when a complete rupture before the head descended upon the perineum is anticipated, so as to bring the parts into accurate apposition.

In two cases of elderly primiparæ, in which I was certain that an extensive laceration would result, I introduced two strong catgut sutures in a curved fashion deeply into the pelvic floor, anterior to the rectum. The first traversed the tissues just within the nympha near the lower end, one-half of an inch in front of the anus, and came out at the same point in the nympha on the opposite side. The second started about a half inch lower down, closer to the posterior commissure, and followed the same course, anterior to or above the first one, but more deeply situated. The loop thus formed was elliptical and included the sphincter vaginæ and transversus perinei muscles, perhaps some anterior fibers of the sphincter ani muscles, and, possibly, also fibers of the levator ani et vaginæ muscle as well as some of the pelvic fascia. The result was gratifying in both cases, as it gave full control over the lacerated and retracted muscles, bringing them in close coaptation, and simplified the subsequent steps in the repair of the vaginal injury.

I fully recognize the importance of securing union of muscle and fascia separately, to assure a strong pelvic floor. This method does not produce a bundling of these tissues, but only holds the parts together until the other sutures are introduced, both perineal and vaginal. The method is of value in inevitable laceration, but the exercise of ordinary care will save many cases from injury if the obstetrician will control the advance of the head, thereby preventing too rapid extension of the same, and also caution the patient against applying too much expulsive effort while the occiput is passing through the distended vulva.

The forehead should not be allowed to slip over the distended perineum until the occiput is expelled. If this precaution is observed, it will rarely be necessary to "shell out" the head by pressure through the rectum.

Hofbauer, in the *Centralblatt für Gynäkologie*, No. 5, 1901, describes the following technique for the preservation of the perineum: "The right hand is laid flat on the perineum, the frenulum is left

plainly in sight, and exerts a pressure forward upon the head through the perineum." When the posterior angle of the large fontanelle appears and the greatest circumference is passing, the head is rotated to one side to throw the strain off the perineum. This "anticipated external rotation" is about 40 degrees. The results, he says, are very good. After the use of forceps, the instrument is removed, when the large fontanelle appears and then the method described above is followed.

In occiput posterior positions, the head should not be extended, the anterior fontanelle not delivered, until the margin of the perineum rests in the nape of the child's neck. As this is the time when haste to deliver will do damage, it is better to allow half an hour to pass, after the head has reached the pelvic floor, before it is permitted to be expelled.

The instructions given in works on obstetrics are, support of perineum, pressure on advancing head, chloroform, forceps, and episiotomy. With the careful and patient obstetrician these mean very much, yet in some cases any and all of them are of no avail.

In breech presentations undue haste will give considerable annoyance, and if the breech seems too large for the canal, Malcolm MacLean's method of dilating the latter by withdrawing the closed fist several times is excellent.

We should use every effort to keep the head flexed, by well and properly directed abdominal pressure. When the cervix has closed around the neck of the aftercoming head, the extent of the injury is influenced by the amount of traction power exerted.

The methods of operative repair of postpartum injuries of the genital canal are so variously described by authorities, that I will confine myself to the treatment adopted in my own practice, and I believe my technique differs but slightly from others.

Lacerations of the cervix which are not extensive are not to be repaired immediately, but left for secondary operation, for spontaneous repair sometimes occurs in very bad cervical tears. If hemorrhage is excessive the uterovaginal tampon of sterile or 5 per cent. iodoform gauze left in for twenty-four hours, usually controls it.

In one case in which the laceration was quite severe, the tampon did not control the bleeding, and it was necessary to press down the uterus, grasp the lips with large bullet forceps and run a catgut ligature around the angle of the tear before hemorrhage was stopped. I used vaginal retractors, and had the patient placed on the table, in order to render these postpartum manipulations less difficult, for it is this inconvenience which interferes with the proper obstetrical work in private practice.

Immediate repair of the cervical laceration is rarely successful, whereas a trachelorrhaphy two months later gives excellent results. Injuries to the fornix and vagina are treated according to their depth. If superficial, they will heal quite readily, leaving more or less scar tissue, if strict aseptic care is employed until the tenth day.

In cases in which I can put in a fine catgut stitch, without leaving any small pockets, where the accumulating and putrefying lochia may act as a commencing nidus for producing sapræmia, or what is much worse, puerperal septicæmia, I do so, but if they are deep, I begin on the second day by irrigation, and with the aid of a speculum place in them iodoform or sterile gauze, which is renewed daily. In this way they heal by granulation.

The two-bladed speculum is not applicable in shallow vaginal tears, as distension of the mucous membrane prevents recognition of them.

When I encounter cases of relaxation of the pelvic floor, in which the submucous muscles and fascia have been lacerated without any surface injury, I fully explain the situation before I finish my attendance, warn the patient of the probable consequences if it is not attended to at a subsequent time, and advise the appropriate operative treatment before the uterine displacement and prolapsus have begun to develop.

When the pelvic floor and perineum are torn, my treatment varies with the degree of rupture. If but slight, hardly necessitating a single stitch, I advise aseptic cleanliness, bathing the vulva with an antiseptic solution at regular periods and also after each micturition.

The toilet, after an evacuation, should always be made in a downward direction away from the vulva, and finished with a local bath of antiseptic solution.

In cases of rupture of the second degree, I do an immediate perineorrhaphy, unless the patient is too weak from loss of blood or from shock after a difficult accouchement, in which case, I insist upon its being done within twenty-four hours. This is very important, and even if the result is not perfect, at any rate the likelihood of septic absorption through the broken surfaces is reduced.

As kind as nature may be, we cannot rely upon her entirely, for simply keeping the knees tied and depending on surgical cleanliness will not bring about primary union in these cases, but sutures will, if they are properly placed, and are at all effective.

Although the Peaslee needle is recommended by some, and I used it until ten years ago, the three-sided curved needles, with a carrier, give me more satisfaction. The carrier enables one to use silver wire, which I prefer for external work, because it can be more easily removed, and there is no danger of the knot opening.

Silk worm gut, although it has a tendency to cut through the tissues, has been highly recommended and much used in this work, but my results have been so uniformly good in immediate perineorrhaphy with silver wire that I still adhere to it.

It is not always convenient, but for this work my preference is to have the patient on the table in a dorsal position, with a twisted sheet to hold up the legs, even if the operation is done immediately after delivery.

The vagina is first irrigated, I then introduce a ball of sterilized absorbent cotton, placing it close to the cervix, then a Barnes' bag into the rectum; this, when inflated, causes the floor of the wound to stand out more prominently, and enables me to carry my needle around to the opposite side with more ease, and also gives warning, by its collapsed condition, if I have, in the attempt to take a deep bite in the muscular tissues, perhaps entered the rectum. My sutures are interrupted and buried in their entire course, although it is allowable to have them come out at the base of the wound and re-enter on the other side. They are introduced through perineal skin principally. I place catgut sutures in the vagina, when I find it necessary to strengthen the vaginal margins of the closed wounds, to avoid pockets, and even introduce them deeply, if necessary, to grasp the muscles again more securely in their original relationship, instead of having them grouped.

The first suture is placed near the anus; the others one-half inch or less apart, until I reach the nymphæ, thus the topmost suture includes the lower

ends of the labia majora. The vaginal sutures are first tightened, and then the silver wire twisted and cut off. If the two large catgut sutures mentioned above have been inserted, they are now withdrawn, as they were used only for controlling purposes.

Examination intravaginam will show the entire length of the wound closed, and possible pockets in which lochia may accumulate must be searched for. The pledget of cotton is then removed slowly, and following the axis of the vagina; then the Barnes' bag is emptied and withdrawn. After thorough cleansing, strips of iodoform gauze are placed on each side and over the shortened, twisted ends of the protruding wire to protect the thighs.

The limbs are not tied, nor do I advise catheterization; aseptic cleansing and frequent renewal of the dressing constitute the after-treatment until the sutures are removed on the tenth day.

In complete rupture I have several times sewed the rectum with catgut sutures pointing into the cavity. I pass two stout catgut ligatures (I use the chromicized ten-day catgut) into the retracted ends of the severed sphincter muscle, and after tying these very tightly, proceed as in the operation for second degree rupture, except that a Barnes' bag is not advisable. My experience teaches me, however, that most cases do not heal by primary union, and the patient is, therefore, more liable to infection from the gut. Should septic symptoms occur it then becomes necessary to open up and remove all the sutures. Therefore I simply direct that the bowel and vagina be kept as clean as possible, and I keep the patient under observation until such a time as a complete plastic operation can assure a good result.

The length of the paper compels me to omit many details, and prevents a proper consideration of injuries of the vulva, labia minora, and majora, and the urethral orifice, yet, as they do not bleed much, except when the bulbi vestibuli are involved, and as they should, if deep, receive the same surgical repair, they are not very important.

In closing I wish to reiterate and earnestly advocate that the general practitioner approach his parturient case with patience, never hurry except when the saving of life makes urgency in action a necessity, and never fail to learn exactly, by examination, the condition in which this physiological process has left the genital canal, and to remedy any unfortunate result by prompt attention and repair.

## THE SELECTION OF THE ANÆSTHETIC IN CHILDREN.

By S. J. KOPETZKY, M.D.,
NEW YORK.
ANÆSTHETIST TO THE HARLEM HOSPITAL, NEW YORK.

In selecting the anæsthetic to be given to children, the anæsthetist and surgeon are confronted with a problem of grave import. It is here proposed to demonstrate that the generally accepted use of chloroform with children should not be adhered to. The advantages claimed for it are few as compared with its dangers, and although, as generally stated in textbooks, it is safest in children, my experience does not bear out this contention.

Those who use chloroform continuously are most emphatic in warning against its dangers generally, and especially in the hands of the inexperienced. The many operations to which children must frequently submit and which the general practitioner performs himself, with the aid of another no more qualified in its use than himself, cause the lives of these little patients to be endangered by the unhesitating acceptance of this too generally advocated procedure.

Among the various conditions in which chloroform is indicated, it has been found to be comparatively safest in obstetrical practice when the condition of pregnancy has hypertrophied the heart wall and increased the vascularity of the nervous system and when the woman, welcoming the relief afforded, *gladly* accepts the anæsthetic.

While it is true that the greater vascularity of the nervous system in children, combined with their inferior muscular development, as compared with the adult, would seem to render chloroform safe, yet the element of fear with its series of vasomotor phenomena is more than enough to counterbalance this. Children over two years of age are invariably frightened. Of five hundred cases anæsthetized by the writer at the Gouverneur Trachoma Hospital fully 70 per cent. exhibited phenomena of fright. They struggle with a strength born of desperation, they fix their thoracic muscles in a tonic spasm, and when, exhausted, finally take a breath, they inhale an overdose of the chloroform which has been faithfully dropped on the mask during the entire procedure. Not only is it extremely easy thus to give an overdose, but the struggle, as stated by Hare, exhausts the vasomotor system, strains the heart, and may cause its dilatation. Again, children are more easily brought under and consequently more easily given a fatal dose. Add to this the tendency to push the anæsthetic so as to get the child under as quickly as possible, and you have the elements which in many an operation, substantially devoid of danger, jeopardize the patient's life; notwithstanding the fact that a child can be resuscitated after accidents from chloroform under which an adult succumbs.

St. Germain stated that he anæsthetized six thousand infants with chloroform without a single death. For the same period of life, that is, up to the twelfth year, there is not one death recorded from ether, while from chloroform there are twenty-one deaths found in literature, as reported by Weir in 1900. Nor must the testimony of those employing only *one anæsthetic* habitually, be given too much weight; naturally enough, employing but one anæsthetic, they become so proficient in its use that results obtained by them are not borne out in fact by others whose experience is with a larger field of anæsthetics. And it must certainly be regarded as antiquated to employ one anæsthetic for all cases, even in subjects whose vital organs are normal.

The danger from chloroform is greatest in the very early stage of its administration, due to its action on the vagus-inhibitory mechanism, and a failure in respiration will happen as frequently before as after the stopping of the heart, as was shown by Embley. With chloroform, vomiting is sometimes accompanied by symptoms of severe cardiac depression. Cases are on record in which fatal syncope has arisen both during and after chloroformization, and in one of the cases the autopsy showed no lesion of the heart. This may occur quite a time after the anæsthetic has been stopped. At the Gouverneur Trachoma Hospital I witnessed one such case in which, about ten minutes after the anæsthetic had been stopped and the operation completed, vomiting set in, followed by syncope. Fortunately the nurse in charge was alert, and prompt measures afforded relief. I may note in passing that chloroform was given to this child because of an albuminuria found at the time of operation.

In the administration of the ether we are met at

the outset with a series of objections. It is most disagreeable to administer. The irritation caused by it excites a flow of mucus which in the smaller bronchi of children is apt to cause obstruction and consequent danger. Its administration requires more time and its rapid evaporation may cause an ether-pneumonia.

In recent years the view has been advanced that the mortality of ether was as great as that of chloroform when the after-effects of the former were taken into consideration. Cases in which pneumonia followed the administration of ether have been reported repeatedly, some of which developed but a few hours after etherization. Yet Dudley Buxton, in criticising these reports, states that few are found to be really due to ether, but rather due to the removal of the patient through cold halls into cold wards, to shock, etc., suggesting the possibility of pulmonary congestion and subsequent infection. J. F. W. Silks states "that there is no evidence that lobar pneumonia occurs after ether with greater frequency than might be expected from the normal rate of incidents of the disease." It is true that the intense cold produced by the rapid evaporation of ether-vapor in the lungs and the consequent chilling of the blood-stream there, predisposes to congestive conditions, but with a *closed* inhaler this evaporation can be controlled, and by mixing the expired air with the ether inhaled through the use of any one of the many apparatuses on the market this condition will not occur. Over twenty thousand children were anæsthetized at the Gouverneur Trachoma Hospital by the nitrous-oxide-ether method with a closed inhaler, and not one case of ether-pneumonia developed.

The safest anæsthetic known is nitrous-oxide. Neither deaths nor bad after-effects have been reported from its use. We are indebted to Clover for the valuable suggestion of preceding ether with it. Supplying what is deficient in ether, it is particularly appropriate for inducing anæsthesia. It is agreeable to take, and with children one or two breaths are sufficient to cause loss of consciousness. This is not attended with excitement or struggle and is free from risk to life. In children, from 5 to 10 per cent. air may be given with it. Thus administered, the cyanosis, jactitations and opisthotonos do not occur. If oxygen be given in greater quantity, struggling does occur, but it is not attended with those dangers which the anæsthetist fears when the struggle takes place under chloroform. Its peculiar adaptability to the continuance of anæsthesia with ether is based on the fact that paucity of oxygen is a benefit rather than a danger. It lessens mucus flow and does not produce circulatory phenomena of dangerous kinds.

When we follow the administration of nitrous-oxide with ether, the surgeon has at his command an ideal anæsthetic for children. It combines the rapidity of chloroform without its dangers, with the safety of ether. With its use vomiting is lessened, since the quantity of ether taken in a given case is smaller and consequently the after-effects are correspondingly less. I have seen but two cases of respiratory irregularity in five hundred when this method was resorted to.

To recapitulate: That to use chloroform is safer than to employ ether with children, is not borne out by close observation, and especially is this true with robust and healthy children. Chloroform is dangerous because an overdose may be too easily given. Cardiac failure may set in at the very beginning of the anæsthesia, because of the violent and dangerous struggle which takes place in frightened children.

Death occurs suddenly and without warning. The tendency to push the anæsthetic is too tempting. Cardiac syncope following vomiting may occur at any time during or after the administration of chloroform and result fatally.

On the other hand, nitrous-oxide induces anæsthesia rapidly and without any dangerous symptoms, and when followed by ether from a closed inhaler, rapid evaporation from the lung is avoided and ether-pneumonia does not occur. By preceding ether with nitrous-oxide, the amount of ether required is lessened, diminishing the after-effects. With chloroform, any departure from the depths of anæsthesia which is proper in any particular case is attended with difficulties more or less grave, while with ether we may err on the side of too light or deep an anæsthesia with but small risk to the patient.

In conclusion, I wish to sound a note of warning against the practice of commencing short operations on the nose, throat or eyes, before complete anæsthesia is induced; and the practice of some operators in these specialties, of using chloroform with the patient in the upright position, cannot be too strongly condemned.

## AN OPERATION FOR REMOVING THE TONSILS.

By WILLIAM H. STEERS, M.D.,
BROOKLYN, N. Y.

For operation on those diseased masses known as hypertrophied tonsils, various tonsillotomes have been devised, any one of which will serve a more or less useful purpose in certain cases. These various instruments are advocated by individual operators, as early instruction and subsequent use have made the particular instrument seem most desirable in his individual case. Yet, in the majority of cases, other instrumental interference than can be accomplished with the tonsillotome alone, is necessary.

For the removal of such hypertrophied tonsils as are not attached to the faucial pillars, and which project abruptly into the throat, the tonsillotome is an ideal instrument, working quickly, with a minimum of shock, and without anæsthesia. But in those cases in which a considerable portion or all of the tumor is enveloped in the pillars of the fauces, and in those cases in which adhesion bands pass from the pillars to the tonsil, the tonsillotome is unsatisfactory; either entirely failing to grasp the tumor, or slicing off a portion only.

The reasons for operating on these masses, I take it, are: (1) To furnish sufficient space for deglutition and respiration. This is a reason in extreme cases only. (2) To afford free action to the palatoglossus and palatopharyngeus muscles, including those fibers of the palatopharyngeus known as the salpingopharyngeus; where loss of such action, due to these masses, has impaired audition or phonation. (3) To remove a useless mass, which serves merely as a culture ground for disease germs.

If a portion only of the mass is removed, the first

and generally the least important of these objects will have been attained, but the second and third, which are by far the most important, will not have been accomplished. The remaining tonsillar tissue, infiltrated with cheesy deposits and alive with germs, becomes inflamed as often as before, and will in many cases, rapidly enlarge to its former or even a larger size; and the patient will have been subject to the inconvenience and dangers of an operation without any permanent gain.

In consequence of this inapplicability of the tonsillotome alone, to a majority of cases, I have during the past six or seven years used almost exclusively the simple knife and forceps according to the following method; which may be satisfactorily employed in all cases.

In addition to the knife and forceps I also employ a hook-like knife which I modeled from the lines of a strabismus hook, making the handle longer and stouter, and giving a knife edge to the concavity and end of the hook.

The patient being anæsthetized, and on a table, the foot of which is elevated, is placed on his side, his mouth held open by a gag, and his tongue pressed downward and forward with a depressor.

The finger of the operator is then passed over and around the tonsils to detect any pulsating vessels. The under tonsil, which, if the patient is on his right side, will be the right, is then seized with a volsellum, preferably of the pattern known as Kelly's, and drawn toward the opposite side. The described hook-knife is then passed between the tonsil and the anterior pillar of the fauces, just beneath what I term the basement membrane of the tonsil, which is probably nothing but the mucosa between the pillars of the fauces. The tonsil is thus almost completely separated from the anterior pillar.

Some care is here necessary, that the knife be passed not into the tonsil mass, but beneath its basement membrane.

The finger of the operator is then introduced into the wound, and making sure that pulsating vessels cannot be felt, and using the finger as a blunt dissector, the mass is turned out, thus leaving it attached only to the posterior pillar, and by mucous membrane only, which is divided by the ordinary blunt-pointed tonsil bistoury.

Hemorrhage is free at first but ceases promptly. Should any bleeding vessels present, they are seized with forceps and treated as in any other situation.

When removed, it will be found that the base of the tonsil is covered by a thin membrane, and that the dissection has been carried on entirely outside of the tonsil which has thereby been entirely removed.

Without turning the patient the other tonsil is then removed in the same manner.

After the wounds have healed, it will be found that the pillars of the fauces stand out in their proper position, and that their muscles act freely.

When this operation is properly done there will be no return of the tumor.

The dangers of any operation on the tonsils are, first, severe hemorrhage, which may be primary or secondary, and, second, infection.

Ordinary cleanliness will guard against the latter. But the first, as a perusal of the literature of the subject will show, has occurred in the practice of the most skilled.

Fatal hemorrhage has been reported from division of a misplaced internal carotid artery.

Severe hemorrhage, primary or secondary, may occur from the section being made through the diseased tonsillar tissue, thus leaving a portion of the mass, and dividing blood vessels whose contractile power is impaired.

By the above-described procedure—that is, careful palpation and dissection outside the tonsillar tissue—I believe we are in a measure guarded against this danger, which, remote though it be, is to be considered, and at the same time we have done that which is logically indicated, namely, completely removed the tumor.

537 Franklin Avenue.

**Is Atrophic Rhinitis Always Autochthonous?**—In a paper read before the Madrid Congress, W. Freudenthal reviews our present knowledge concerning this form of nasal catarrh. Ozæna, says he, is an atrophic rhinitis influenced by atmospheric conditions, and he proposes for the general clinical condition the name xerasia. In the commencement of the malady the osseous turbinals are attacked, and the condition is aggravated by the dryness of the air making itself felt on (1) the nasal fossæ, causing simple septal ulcers, epistaxis, etc.; (2) parts adjacent to the nose, as head, ears, lips, and teeth, and (3) probably on distant organs. In order that there may be a true ozæna, there must be present a bacillus analogous to the pneumobacillus of Friedländer. This bacillary invasion occurs in growth. In certain cases it may be that the bacillus is conveyed from the vulva to the nose. In ozæna the sinuses are often secondarily involved. Finally ozæna can be looked on as a specific and autochthonous malady resulting from an atrophic rhinitis.—*Revue Hebdomadaire de Laryngologie.*

**The Upper Respiratory Tract as a Source of Systematic Infection.**—F. DeHavilland Hall states that though typhoid fever is almost invariably propagated by means of the stools and urine, there is sufficient evidence to show that the Eberth-Gaffky bacillus may find its way into the system through the respiratory tract. This is the more likely if the vitality of the laryngeal mucous membrane is lowered owing to previous inflammatory mischief. Budd holds the view that under certain conditions typhoid fever is infectious, and they should lead to the expectoration being disinfected. Though definite evidence is wanting, clinical experience points conclusively to the poison of measles and whooping-cough being received via the respiratory tract. In influenza the trouble in many cases has appeared to start in the nasopharyngeal space. The writer believes that adenoid vegetations and enlargement of the faucial tonsils render the individual more liable to contract influenza and many other infectious diseases. In diphtheria, in the majority of cases, the Klebs-Löffler bacillus implants itself in the tonsil, and probably enters its substance through some abrasion of the epithelium. At the onset the disease is a purely local one. Two cases were mentioned in which, after the application of the galvanocautery to the nasal mucosa, scarlet fever attacked the individual. The writer believed that the germ entered the system through the wound caused by the cautery. The intimate connection between the throat and acute rheumatism was emphasized. Notes of two cases were read showing that septic and pyæmic processes may be the result of infection through the upper respiratory tract. The important part played by chronic nasal affections in the production of facial erysipelas was insisted on. Primary nasal tuberculosis and primary laryngeal tuberculosis sometimes occur. The tonsils are liable to tuberculous infection. The recognition of the tuberculous nature of some adenoid vegetations, and the possibility of the system becoming infected through them, should constitute an additional reason for the prompt and complete removal of these growths.—*Medical Press and Circular.*

## DETERIORATION IN PHYSIQUE OF THE BRITISH RACE.

THE lay and medical journals of Great Britain have alike been eagerly debating the point as to whether the national physique has deteriorated. The question has been discussed in all its phases, distinguished authorities have given their views on the matter, and the outcome is that much light has been thrown on this very important subject. Sir Frederick Maurice was one of the first to draw attention to the fact that the physical qualifications of recruits for the army were steadily declining, and he has followed up his first criticisms by others which are still more adverse. The Boer war and the report of the commission which sat thereon, and the memorandum of the Director-General, Army Medical Service, both of which state that a large proportion of the men who volunteered for the South-African campaign were weaklings, have aroused the keenest interest among all classes of British society. General Maurice asserted, in an article contributed to the *Contemporary Review*, January, 1903, "that only two out of five men enlisting remain in the army as effective soldiers at the end of two years service," or, in other words, that 60 per cent. of the men offering themselves for enlistment are not in a fit physical condition to complete their term under colors.

Those who look upon the dark side of life argue that these facts show that the British race, as a whole, has physically deteriorated, while the optimists declare the gravity of the situation is grossly exaggerated, and that if there has been a deterioration in physique of recruits, it is mainly owing to the enlistment of mere boys who in days gone by would never have thought of offering themselves as soldiers. There is yet another and more reasonable body of debaters who regard the rush in recent years of country people to the towns as the chief cause of the physical decadence of volunteers for the army; at the same time it is contended that this does not prove that the British race generally is inferior in bodily vigor and endurance to its representatives of fifty years ago. Statistics, indeed, would seem to show that the average height and weight of the population of the United Kingdom have increased within the past thirty years. The well-to-do inhabitants have undoubtedly added to their stature, and are probably as good physical specimens of the human race as can be found anywhere, but this improvement is counterbalanced by the deterioration in physique of a considerable portion of the working classes, who have abandoned country life with its health-giving properties, in order to live in towns often under conditions the reverse of hygienic. The inquiry, therefore, that the British Government is said to be about to request the chiefs of the medical profession to make is, so far as the national physique is concerned, perfectly justified by the circumstances.

The London *Spectator*, the most brilliant, and perhaps the sanest of the London weeklies, takes a common sense view of the matter, and while refusing to be alarmed, or even greatly disquieted by the prognostications of evil at the present time so freely scattered about, allows that an inquiry into the loudly proclaimed British physical deterioration is eminently fitting. This journal points out that two immense changes are passing over the population, and it is necessary to ascertain in a definite, and for the time final, way what the effect of these changes upon the health of the population really is. The people are rapidly quitting the country for the towns; it is not merely that great cities are growing till it is becoming a serious difficulty to supply them with good water, but the minor towns are growing till in other countries they would be accounted cities. The Earl of Meath recently illustrated in a convincing way the manner in which the exodus from country to towns has been going on in England. He supplied the following figures: "In 1881 the urban population of England and Wales was 8,990,000 out of a total population of 17,927,000, or 50 per cent.; in 1891 it was 25,000,000, out of a total population of 32,000,000, or 77 per cent."

The mode of life in a busy town does not only tax brain and nerve power much more severely than does country life, but the diet of the urban working population is not nearly so nourishing as that of their rural brethren. The *British Medical Journal* in a recent issue rightly emphasizes this point. The working classes of towns do not compare favorably as cooks with those of the country, and perhaps the greatest drawback to their physical welfare is that they consume a far larger quantity of spirits and tea than the laborers in rural districts.

The *Spectator*, however, thinks—and with this view the *British Medical Journal* is more or less in agreement—that one of the most potent causes of physical degeneration among poor of towns is the strict attention which is paid to the education of the young. In Great Britain growing boys and girls are compelled by law during nine years to remain in school for several hours a day. This confinement and strain upon the brain bears with especial weight upon the children of the poor. Ill-fed, and descendants of illiterate and untaught persons, the effect of mental development cannot fail to effect injuriously their bodily health. The tendency of the age has been too much toward mental training, and physical improvement, which is quite as important, has been neglected. The *Spectator* urges that gymnastic training and a quasi-military drill should make a part of the compulsory education in every school, and then goes on to say: "We want to be rid of 'nerves' as well as of typhoid fever, and to give the young conditions of health other than pure water and well-trapped drains. . . . What is wanted is clear information on two points—whether the transfer of the population

to towns and the new practice of educating the children of the poor on a purely literary basis do or do not deteriorate the public health."

In the *Journal of the British Royal Army Medical Corps* is an editorial dealing with the question of national physique and military service. The writer of this article, of course, cannot deny that there is a very large number of rejections of recruits for the army on account of physical defects, but states that the annual tables concerning recruits show no marked changes in recent years, either in respect of the social stata from which recruits are drawn, of the proportion which various occupations or groups bear to the whole number examined, or the ratio rejected in each of such groups.

It is, nevertheless, manifest that the supply of human material to the army is not satisfactory in quality, and it seems also to some extent certain that the poor population of Great Britain has deteriorated physically, owing undoubtedly, in the main, to the transfer of so large a proportion of the inhabitants to towns. Insufficient and unfit diet is also an important factor in the case, as is the present-day custom of overstraining the mental capacity of the young, oftentimes under insanitary conditions. The inquiry to be instituted by prominent British medical men into the matter will be of interest to the world at large, for it must be borne in mind that although in England and Scotland the situation as regards town population is most accentuated, yet the tendency in every civilized country is to desert the country for the towns. The problem then to be solved is how to render city life as healthy as possible.

## CANCROIN TREATMENT OF CANCER.

Dr. A. Adamkiewicz defends, in the *Deutsche Aerzte-Zeitung* for June 15, his method of treating cancer by injections of cancroin. The damage done by the disease and the disease products, are threefold, local-anatomical, local-functional, and general. The action of cancroin takes place in the reverse order, and cancroin fulfils its special task if it hinders the injurious influence of the cancer products upon function and the general condition of the patient. The "cure" of cancer (that is, the elimination of the dead cancer and its replacement by formative tissue) is exclusively a question for the reparative powers of the organism. It is consequently not reasonable always to demand such "cure." After these preliminary observations the author gives the details of the results obtained in eight cases, the first four of which we abstract as illustrative:

*Cancer of palate.* Male, aged fifty-two years, attacked in January, 1902, with pain on swallowing on the right side, in the right ear, and extending to the whole right face. Examination showed cancer of the right side of the soft palate, which was operated upon the same month but recurred two months later. January, 1903, the patient showed dysphagia, great tenderness over the styloid process, and the jaws could not be separated. Through a cleft between the teeth a fungoid cancer, larger than a crown piece, could be seen on the soft palate just behind the right end of the upper alveolar process and in front of the anterior palatal arch. Cancroin injections, begun January 16, relieved, first of all, the pains; then the growth became metamorphosed into white fat, the lower jaw became movable, and toward the end of the second week the patient showed how he could introduce a finger between the teeth, and the use of solid food could be resumed; and by the beginning of February he could already chew meat on the healthy side and, a few days later, upon the right side also. About February 4 nothing was left of the tumor but a clean, granulating ulcer, which healed completely by the beginning of March. By the end of April pains returned in the original focus, and here, unfortunately, the record ends.

*Cancer of tongue and cervical glands.* Man, aged fifty-two years; violent pains in tongue, leading to examination September, 1902, which revealed cancer already extending over the whole tongue, and to the bottom of the mouth cavity and the neighboring glands; operation. January 18, 1903, the tongue was a blue-red, tumor mass, knotty, immovable, grown to the bottom of the mouth cavity, which it filled, forming only an appendage to a tumor mass larger than a fist formed from the bottom of the mouth cavity. There was, besides, a tumor bigger than a fist on the right side of the neck just behind the right ear, connected with the first tumor through an infiltration filling out the space behind the ascending ramus of the jaw. Speech was completely unintelligible, food was confined to an insufficient quantity of liquids, and the attacks of pain led to wild outbreaks, followed by the patient's falling to the ground unconscious; attacks in which much trouble was experienced in reviving him. Under cancroin the tongue regained somewhat its motility, the infiltration decreased markedly and the tumor behind the ear softened so much as to permit of the evacuation of its contents by successive punctures. By the middle of March it had almost completely vanished, as had also a great part of that of the lower jaw region.

*Cancer of stomach and liver.* Man, aged fifty-two years; anorexia, August, 1902; October 20, on examination, induration of whole anterior wall of stomach with painfulness on pressure; increase in size and resistance of the liver; high-grade anæmia, and œdema of both ankles; weight 71 kgms. Under cancroin the stomach induration vanished, except one walnut-sized, hard spot on the greater curvature; the liver decreased considerably in volume and retained an uneven surface (infiltrated tissue sinking in, leaving carcinomatous patches as elevations), the tuberosities of which gradually diminished in number and size; at one place, close to the costal border, a depression the size of a hen's egg was noted. The patient regained appetite, and on November 19 weighed 73.75 kgms. Adamkiewicz has repeatedly observed the vanishing of cancerous infiltrations and tuberosities from the liver, and the consequent reduction in a short time of the increased volume acquired through the disease.

*Cancer of intestines.* Woman, aged fifty-two years, sick since September, 1902; pain in left hypochondrium, increasing, especially violent upon the region being touched, and unbearable upon defecation. Soon the clothes could not be borne, and defecation was accomplished only artificially and with the greatest agony. The patient weakened and became bedridden, waiting for death. In November a

tumor in the left upper abdominal region was found but declared to be inoperable. December 15 Adamkiewicz found a large tumor, the size and shape of a pear, to the left of and above the navel, about in the mamillary line, a hand's breadth below the ribs, evidently in the transverse colon. It had the hardness of cartilage. The day after the first injection the tumor was smaller and the pain less. After a few days the patient dressed, ate, and, aided by simple remedies, defecated. By the end of the second week the stools came naturally and had a normal appearance. January 8 only a slight thickening remained, which did not hinder the patient in her household or other work, and Adamkiewicz often met her on the street as late as March.

The author concludes that patient's treated according to his method live longer and in greater comfort, even when not "cured," than those who are given over to their fate without treatment. Certainly his detailed report of cases is sufficiently striking (in spite of the fact that both his diagnoses and his results have repeatedly been called in question by his colleagues) to lead one to await with interest the appearance of his forthcoming work, "Die Heilung des Krebses," of which his article is an advance sheet.

## CARDIAC ARRHYTHMIA AND INDICANURIA.

INTERMITTENCE of the pulse has often been noted in connection with gastrointestinal disturbances. In the *Comptes Rendus de la Société de Biologie* (seance of May 23), however, Prof. Charles Féré relates experiments upon himself which go to show an increase in the frequency of the intermittence in association with indicanuria, indicating the toxic region of the cardiac disturbance. The frequency of the intermittences, observed in the course of a study on the influence of sensory stimuli upon the circulation, varied from day to day; they might be altogether absent during the half or three-quarters of an hour that the experiment lasted. This happens after a laxative or after diminution of the generally too abundant alimentation. Generally the intermittences occurred every five or six minutes on the average; at other times not more than an average of two minutes separated them. Exceptionally they were more frequent following errors of diet or constipation. In general they occurred at irregular intervals, though at times a sort of rhythmic grouping was observed—that is, successive pairs of intermittences were separated by the same number of normal pulsations. The conditions mentioned suggested that the condition was due to an intoxication from the alimentary canal, variable in intensity from day to day with variations in the hygienic state. Thinking that the verification of this hypothesis should be furnished by the urinalysis, this was made sixteen times. The estimation of the indican was always made in the same way (hydrochloric acid, Labarraque's solution, chloroform). Nine times the characteristic reaction was obtained; seven times it was lacking. The days when it was lacking there were no intermittences, or only two or three, in the course of the experiments. Where the reaction was obtained the intermittences were more frequent (at least every two minutes). While in the absence of quantitative estimations one cannot say that a constant relation exists between the amount of indican and the frequency of the intermittence, nevertheless there was evident a relation between the presence of the indican and the frequency. Twice along with the indican the presence of urobilin was noted.

## OVERCROWDING IN CITIES AND ITS REMEDY.

At the annual conference of the Royal Institute of Public Health recently held in England, one of the most important matters discussed was that of city congestion. So far as this matter is concerned, Great Britain presents the situation in its most accentuated aspect. The country is thickly studded with towns, some of which are overgrown, and whose inhabitants are massed together in an area so circumscribed as to be inimical to health and especially deleterious to the upbringing of the young. How to enable the town population of the civilized world in general, and of Great Britain in particular, is, in fact, far more important, though, on the face of it, not so spectacular as any of the burning political questions of the hour. As to whether England is to have free trade or protection, the subject which is now convulsing that country, sinks into comparative insignificance when contrasted with the problem of city congestion and the most effective mode of relieving it.

The speakers at the conference referred to advocated several remedial measures. Mr. Austin Taylor, M.P., "suggested that municipalities should be allowed to buy land three miles outside their boundaries where streets could be laid out on model lines, trees preserved, and a general style of architecture insisted upon. There must be expansion to cure congestion, and for that purpose he also advocated the compulsory acquirement of suitable areas on moderate terms, the reduction of interest on public loans for demolition and rehousing, and rating of vacant sites on their capital value, by which model dwellings could be erected at not greater rent than one shilling (twenty-four cents) per room weekly."

Dr. James Niven, medical officer for Manchester, made a speech on similar lines, and said "it was generally recognized that an effort should be made by the sanitary authorities to house as many as possible of the poorer working-class families on the outlying parts of these districts under the improved conditions of light, air, space, and construction of dwellings. So far, efforts in this direction had been the result of private enterprise and confined to persons above the laboring classes. A great impulse had already been given to the movement outward by the development of electric trams.

The speaker then described in detail the steps which had been taken in Manchester to improve the sanitary surroundings of the poor by transferring the working population to outlying districts. From a consideration of the system of building up and developing colonies at a distance from the city, initiated by Manchester and some other large centers of population in Great Britain, it would appear that the authorities of these places have shown a wiser appreciation of the facts o the case than have those who are responsible for the local governing of London and, it may also be said, of New York.

Of course, London is so large and unwieldy that it can hardly be compared with any other large city of the world, unless it be with New York, while the conditions in New York, owing to its conformation, make its comparison with London somewhat difficult.

The tendency, however, of the inhabitants of all civilized countries to move into towns renders the question of housing them properly and of enabling them to live under good hygienic conditions, perhaps, quite the most important of the present age. The United States, immense country as it is, is faced with a city housing problem, aggravated in New York especially, by the continuous influx of indigent immigrants who, in their own lands, have lived in a state which should not be tolerated in highly civilized and self-respecting communities. The matter of overcrowding in New York and in other large towns of this continent must be energetically dealt with by the city governments.

---

PILOCARPINE IN THE TREATMENT OF PNEUMONIA.

Dr. E. Curtin in the *Lancet*, May 16, discusses this subject from the standpoint of his own experience. Pilocarpine as diaphoretic is well known and widely used, but its therapeutic value in the treatment of other diseases, and especially of pneumonia, has been rarely tested. Pelzyl has recorded in the *Lancet* of a recent date his experiences in an Austrian military hospital, where he gave, with good results, 0.0125 gram—equal to one-fifth grain in solution—of pilocarpine hydrochloride by the mouth to patientssuffering from pneumonia

Curtin states that he made use of the drug in several cases under his care in the South-African war during 1901–'02. The administration was by means of hypodermic injections of one-tenth grain of pilocarpine nitrate in solutions of tabloids of that strength. He draws attention to the fact that the disease in colored races exhibits some differences from that seen in Europeans. In the latter there is more of the toxæmic character than in the former. The high mortality—no less than 50 to 60 per cent.—in cases of pneumonia occurring in the colored races of Africa has been frequently remarked upon. Dr. Curtin gives several instances of treatment by pilocarpine of white and colored patients under his care, in which the results were far more satisfactory among the colored than among the white; this he attributes, as already stated, to the toxæmic symptoms, which were such a marked feature in soldier's affected with pneumonia during active service in South Africa. Two cases of pneumonia in white soldiers impressed the writer in an especially convincing manner that the prognosis in pneumonia does not depend so much on the extent of lung affected as on the amount of toxic symptoms present, and the absence of a healthy reaction in the individual attacked. A low range of temperature is not, thinks Dr. Curtin, necessarily a favorable sign, particularly if accompanied by delirium, scanty expectoration, little cough, and a dry brown tongue. The writer sums up the beneficial effects of pilocarpine as follows: "It relieves pleuritic pain and breathing within a few hours of its administration and also seems to hasten resolution, probably by exciting glandular secretion. Its administration is, in the majority of cases, followed by a rise of temperature of from one-half a degree to one and a half degrees. One-tenth grain hypodermically does not cause profuse perspiration, but rarely fails to reduce the temperature within an hour or two. It also cleans the tongue and stimulates the flow of saliva. One precaution, however, is necessary, and that is, to keep the patient warm, and especially the feet.

---

**Reaping the Reward.**—The Substitute-selling Druggist: Great Pluto! Give me a drink of water to cool my parched tongue! Demon: We haven't any water, but here's something of our own make that's just as good.—*Life*.

TUBERCULOUS INSANITY AND PULMONARY TUBERCULOSIS.

Dr. H. Timbrell Bulstrode, in the Milroy Lectures, said that "Material collected by Drs. T. S. Clouston, F. G. Crookshank, and Eric France, and by a committee of the Medico-Psychological Association, goes to show that the incidence of tuberculosis upon inmates of asylums is very great compared to the general population. Very considerable numbers who die from pulmonary tuberculosis contract or, at any rate, develop the disease within the walls of the institution." Statistics bearing on the subject are quoted. For instance, "Among 70,958 lunatics treated in Prussian asylums during 1901 there were 5,128 deaths, or a fatality rate of 7 per cent. The incidence of tuberculosis was heaviest upon the idiots, as out of 12,212 idiots treated during 1900, 462, or 4 per cent., died, and of these 259, or over a half, died from lung diseases." Statistics from asylums in France reveal a similar state of affairs. "In the report of the Committee on Tuberculosis, it is stated that the annual populations of the asylums from 1894–98 was 57,424, and of this number there were 6,726 deaths, *i.e.* 117 deaths from tuberculosis per 10,000 patients, as against an annual mortality for the whole of France of 43.8 per 10,000, *i.e.* the contribution of the asylums is nearly three times as great as that of the outside population.

Although Dr. Bulstrode has not been able to determine the age-distribution of the asylum population, there is little doubt but that the asylum rate is altogether excessive. It seems too, judging from the final report of the commissioners, that this excessive death rate is artificial, and not what may be termed natural—not of necessity due to a greater tissue proclivity on the part of the insane.

The prevalence of pulmonary tuberculosis among those mentally affected and who have been placed in institutions, has been commented on several times in the editorial pages of the MEDICAL RECORD. It has been pointed out that such a result is almost certain to occur among individuals massed together, with the habits which almost always accompany insanity and idiocy. It may be that persons bereft of reason have a special predisposition to pulmonary tuberculosis, but even if this be so, the situation cannot but be greatly aggravated by the close contact which prevails in asylums. Strict segregation would appear to be the most effective mode of checking the spread of tuberculosis in institutions for the insane, and it is gratifying to learn that this view of the matter has been taken by many enlightened alienists in this country.

---

INCREASE IN SUICIDE.

According to statistics recently published by Mr. Frederick Hoffman in *The Spectator*, suicide is increasing in the United States, the increment having been 4 per cent. for the last year. Among 14,456,183 persons, representing the population of fifty American cities, there were 2,452 suicides in the year 1902. Of this number New York (Boroughs of Manhattan and the Bronx) contributed 456, Chicago 439, Brooklyn 242, Philadelphia 176, St. Louis 142. For the ten years from 1892 to 1902 St. Louis had the highest ratio, namely, 25.7 to every 100,000 inhabitants. In this connection it is pointed out that the statistics may be misleading in so far as some, if not many, of those who commit suicide in the large cities have come from elsewhere, perhaps to seek employment, or for some other reason, and, failing, have ended the struggle by death. The fact remains, however, that

suicide has increased in the United States, and in view of the conditions of stress and ceaseless agitation under which Americans live is likely, for some time to come, to continue to increase.

## News of the Week.

**New Hospital for Philadelphia.**—The announcement is made that the John B. Stetson Company will build a new hospital in Philadelphia, which will be known as the Union Mission Hospital. The building will be a three-story, fire-proof structure, 65.2 by 102 feet, and it will be fitted out with an *x*-ray room, receiving-wards, storage rooms, morgue, laundry, boiler room, and laboratories in the basement; waiting-rooms, office, orderlies' room, pharmacy and dispensary-rooms for diseases of the skin, surgical disorders, diseases of the eye, gynecological disorders, nervous diseases, medical affections and diseases of the ear, nose, and throat on the first floor; rooms for the resident physician, a semi-private ward, rooms for nurses, a woman's ward, and private rooms on the second floor; an operating and etherizing room, a men's ward, kitchen, dining room, a semi-private ward, and private rooms on the third floor; while a roof garden will surmount the building.

**Dr. J. G. Adami and the American Congress of Tuberculosis.**—Dr. Adami of Montreal writes that the publication of his name as one of the honorary presidents of one of the bodies styled American Congress of Tuberculosis was entirely unauthorized by him, and that under no circumstances would he have consented to allow his name to be connected with the organization in question. The congress which he repudiates is the one which announces a meeting in St. Louis in 1904.

**Dr. L. Harrison Mettler** has been appointed consulting neurologist to the Norwegian Lutheran Deaconesses' Home and Hospital, Chicago.

**Behring on Tuberculosis.**—Prof. v. Behring read a paper at the meeting of German Naturalists and Physicians at Cassel on September 25 in which he attacked the view advocated by the Institute for Contagious Diseases in Berlin that bovine tuberculosis is not transmissible to human beings. On the contrary, he agreed with those who think that milk from tuberculous cows is the chief cause of consumption in infants. The digestive organs of the infant, he said, like those of the young of all animals, lack the digestive apparatus and protective tissues which in adults prevent the entrance of infectious bacilli, the mucous membrane of an infant being like a porous filter. He said that he had found inoculation successful in preventing tuberculosis in cattle, and he based on these experiments the hope of being similarly successful in protecting human life, though he referred to the matter with the greatest caution, saying that his experiments were still incomplete and that he did not wish to arouse hopes which might never be realized. His theory is that when cows have been sucessfully inoculated certain immunizing substances pass into the milk and these can be transferred to human beings as an antiserum.

**The King's Sanatorium for Consumptives.**—The first steps in the actual work of erecting King Edward's Sanatorium for Consumptives at Easebourne near Midhurst were taken on September 15, when work was begun on the foundations. The building, which, it is estimated, will cost between $250,000 and $300,000, will probably be opened for the reception of patients in two years, if not earlier.

**The Duties of a Surgeon on a Revenue Cutter.**—It is stated in *The New York Times* that a suit to determine the right of a captain of a revenue cutter to order the ship's surgeon to perform other than his professional duties, has been set down for trial before Judge Andrew Kirkpatrick in the United States District Court in Newark, N. J., on October 5. The action, in which no damages are specified, is brought by Dr. R. N. Sheppard, a surgeon formerly employed on a United States revenue cutter, against Captain Voelker, the commander of the vessel. According to the surgeons'contentions, the ship was detailed to carry a party upon a geological survey to foreign coasts, and he was asked by the captain to take part in making the soundings. He demurred, whereupon, he alleges, he was ordered to do so and refused. When the cutter returned to American waters he was discharged by the Government authorities upon representations of the captain.

**Another Discovery at the University of Chicago.**—The latest newspaper bulletin regarding the usual weekly medical discovery in Chicago states that a professor in the University of Chicago "announces a general conclusion that the physical causes of hydrophobia, vaccinia, smallpox, and yellow fever are not toxic,or from inherent poison, but are infectious. These transmissible diseases, says the doctor, are caused by 'minute living organisms capable of proliferation,' bacteria so small that they work their way through the best-made filters of the laboratories, and so minute that they cannot be detected by the strongest microscope in existence."

**A Medical School on the Midway.**—The University of Chicago has purchased the entire south frontage of the Midway Plaisance between Cottage Grove and Madison avenues, at a cost of $1,000,000 for the land and $450,000 for the buildings. It is announced that the purchase will be utilized in the erection of buildings for the medical department of the university. Rush Medical College will form the nucleus of the institution, and it will be supplemented by the McCormick Memorial Institute for infectious diseases.

**Sale of the Brooklyn Memorial Hospital.**—The Memorial Hospital for Women and Children, Brooklyn, was sold last week under foreclosure proceedings. There was a mortgage on the building of $50,000 and the hospital authorities were unable to pay the interest which was in arrears for several years. There were also other claims against the institution. The property was purchased by the Jewish Hospital Society, which, it is said, will use the building for hospital purposes as soon as the present occupants can find other quarters.

**Chicago Sewage for St. Louis.**—The State of Missiouri has brought an action against Illinois and the Sanitary District of Chicago to restrain the latter from polluting the water supply of St. Louis through the Chicago drainage canal. According to the Attorney-General of Missouri, the morbidity of typhoid fever in St. Louis has increased 70 per cent. since the construction of Chicago's drainage canal. He characterizes "the reckless disregard of human life shown by the City of Chicago" as most criminal.

**Dr. Albert E. Sterne** has been elected by the Board of Directors of the journal editor in chief of *The Medical and Surgical Monitor* of Indianapolis. "Dr. S. E. Earp retires from the editorship after several years of faithful and efficient service with the confidence and gratitude of every member of the directorate." The associate editors are Drs. L. F. Page, William C. White, and Thomas B. Noble.

**A Study of Food Requirements.**—Prof. Russell H. Chittenden of the Sheffield Scientific School at Yale University is about to undertake a series of experiments to determine whether physiological economy in diet cannot be practised with distinct betterment to the body and without loss of strength and vigor. It is, of course, generally conceded that much more food is ordinarily consumed than there is any real necessity for, and that this excess of food is in the long run detrimental to health and defeats the very objects aimed at. It is with a view to gather as many facts as possible on this subject that the study is undertaken. Through the courtesy of Secretary Root and Surgeon General O'Reilly of the army, twenty men have been detailed from the hospital corps and will be sent to New Haven, under the charge of Lieut. Wallace Dewitt, Assistant Surgeon U. S. A., and three non-commissioned officers. The Scientific School has fitted up a house where the men will be cared for during the period of the experiments, which will probably continue for about nine months. The investigation is merely a continuation on a larger scale of observations made in the Sheffield Scientific School last year, and bears directly upon the question of a possible physiological economy in nutrition.

**Medical Department of the University of Illinois.**—By a recent ratification of the articles of affiliation between the College of Physicians and Surgeons and the Chicago College of Dental Surgery, the University of Illinois has established what is claimed to be one of the largest medical schools in the world. The university has purchased the College of Dental Surgery for $200,000.

**The Grant Home for a Hospital.**—Brig.-Gen. Frederick D. Grant and his brothers and sister, wishing to preserve the Grant homestead in Galena, Ill., have given it to the city authorities, who will probably convert it into a hospital.

**Dr. Thomas Gill Nock** of Rome, N. Y., was recently nominated by the Republican convention for Mayor of that city. Dr. Nock is a graduate of the Medical Department of the University of Syracuse in the class of 1883, and is a member of the Oneida County Medical Society and one of the visiting staff of the Rome Hospital.

**A Municipal Drink Cure Institution.**—On October 1 the city of Dresden opened the first governmental institution for the cure of drunkenness on the continent. Patients must be examined as to their sanity and be diagnosed as curable, and must voluntarily submit to a regimen of healthful living, such as farmwork. They will have good moral surroundings and must pay 45 cents a day. Patients may stop three years in the institution.

**Medical Society of the State of New York.**—The semi-annual meeting of this society will be held in the hall of the New York Academy of Medicine, on October 13 and 14, 1903, under the presidency of Dr. A. T. Bristow of Brooklyn. The sessions will begin each day at 10 A.M. and 2.30 P.M. The beginning of the morning sessions will be devoted to miscellaneous subjects. The first afternoon session will be given to a symposium on the Röntgen Ray; the second afternoon session to a symposium on Typhoid Fever. Members of the society and others in the profession are cordially invited to attend. The secretary of the society is Dr. F. C. Curtis of Albany.

**A Health Lesson in Manila.**—In an article on the opposition manifested to the Manila Board of Health, the *Boston Medical and Surgical Journal* says that the work of the board has been hampered chiefly by the action of the Spaniards and wealthy natives, who resent any effort to make them spend money in improving the sanitary condition of houses for which they exact a relatively enormous rent. As a result of their neglect to obey sanitary regulations, a number of prominent Filipinos and Spaniards have lately been sent before the courts and fined. One wealthy banker who had been fined ten dollars appealed his case to a higher court, where the decision of the lower court was not only confirmed, but the sentence increased to one hundred dollars fine, with thirty days in jail in addition; but sentence was suspended for fifteen days on condition that the banker place his premises in good sanitary condition. As this case had been largely regarded as a test case, a reversal of the verdict of the lower court would have seriously impaired the efficiency of the Board of Health. As it is, the opposition has been effectually disposed of, and the eagerness manifested on all sides to comply with any sanitary requirements imposed by the Board of Health is somewhat amusing.

**Degeneracy in Europe.**—At a recent meeting of the Nationalist Congress at Cassel, Dr. Moritz of Alsberg, speaking on inherited degeneracy through social influences, asserted that physical degeneracy in European countries is becoming more and more evident, as marked by a decrease of physical resistance and a tendency to illness and weakness. Alcoholism he declared the chief cause of inherited degeneracy, to cure which alcoholism must be wiped out. He borrowed an idea of the members of some of our State legislatures in the suggestion that a legal certificate of health should be required before a person is allowed to marry.

**A Swindler.**—Dr. Irving Townsend writes that one of the many rascals who prey upon the too confiding doctor is again at work in this city. His story is that the publishers of an illustrated weekly, the regular price of which is $5. are offering a year's subscription for $3 to a physicians, so that patients will find the journal in the reception rooms and may thereby be induced to become subscribers. He exhibits blanks that are apparently official, and accepts checks payable to the publishing company, as well as cash, in payment for the subscription. Inquiry of the publishers has brought the information that the man is a swindler, and that no offer of reduced subscription rate to physicians has been made by them.

**Association of Assistant Physicians of the Ohio State Hospitals.**—The second annual meeting of this association will be held at the Toledo State Hospital on October 7 and 8, 1903. The subjects to be discussed are: delirium tremens, dementia præcox, chorea insaniens, thyroid extract in the treatment of insanity, and general and special methods in the post-mortem examination of the brain and spinal cord. The officers of the association are: *President*, Geo. T. Harding, Jr., Columbus; *Vice-President*, J. F. Kelly, Cleveland; *Secretary*, Isabel A. Bradley, Columbus; *Treasurer*, Nelson H. Young, Toledo.

**The First Woman Physician in the United States.**—A reader calls our attention to an error of fact in a recent issue. In the obituary notice of Dr. Emily R. Robbins of Philadelphia it was remarked that the deceased "is said to have been the first woman physician in the United States." Of course this is not so, for this distinction, we believe, belongs to Dr. Emily Blackwell of this city, who was graduated from the Cleveland Medical College in 1854.

**Obituary Notes.**—Dr. CALVIN SKINNER died at his home in Malone, N. Y., on September 25. He was born in Royalton, Vt., May 29, 1818, and was a

graduate of the University of Vermont and of Dartmouth College, taking his medical decree at Dartmouth with the class of 1841. Dr. Skinner was an enthusiastic Republican in politics, and in 1860 was an alternate delegate to the Chicago convention which nominated Abraham Lincoln to the presidency. When the Civil War broke out he enlisted as surgeon in the One Hundred and Sixth New York Volunteers. In 1884 he took a prominent part in founding the Northern New York Deaf Mute Institution, and acted as trustee and surgeon for many years.

Dr. WILLIAM E. NAUGHTON of this city died of pneumonia on September 23, at the age of twenty-nine years. He was born in Brooklyn and was graduate of the Long Island College Hospital Medical School.

Dr. FREDERICK J. Halton of Brooklyn died at his home in that borough on September 24, of valvular disease of the heart. He was a graduate of the Long Island College Hospital Medical School.

Dr. CHARLES GARDINER of Emporia, Kan., dropped dead on September 24 while performing tonsillotomy. He had just completed the operation and was in the act of arresting the hemorrhage following the excision when he was seen to turn pale and stagger from the room to an adjoining one, in which he fell to the floor dead. In the meantime the wound was steadily bleeding and the patient was almost exsanguine by the time another physician was obtained. Dr. Gardiner was a graduate of Jefferson Medical College, Philadelphia, in the class of 1879, and was widely known for his intellectual and professional attainments.

Dr. ROBERT NEWMAN of this city died at Monument Beach, Mass., on August 28, at the age of seventy-three years. He was born in Germany, but came to this country with other political refugees. He was graduated in medicine from the Long Island College Hospital in 1863, and soon after went to the front as surgeon in one of the New York State Volunteer regiments. In 1869 he took a second M.D. degree from Bellevue Hospital. He was one of the founders of the Medico-Legal Society in 1867. Dr. Newman was widely known through his sturdy advocacy of electrolysis in the treatment of urethral stricture, a method which he preached and practised for a third of a century. He was a prolific writer, having contributed some eighty articles to medical periodical literature. He was a member of the Physicians' Mutual Aid Society; Society for Relief of Widows and Orphans of Medical Men; New York County Medical Association; New York State Medical Association; Society of Medical Jurisprudence; New York German Medical Society, and American Electro-Therapeutic Association.

Dr. MICHAEL C. KREITZER died in Philadelphia on September 24 at the age of seventy-seven years. He was graduated from Jefferson Medical College in 1850. He was an expert metallurgist.

Dr. JOSHUA G. ALLEN died in Philadelphia on September 26 at the age of seventy-three years. He was graduated from the medical department of the University of Pennsylvania more than fifty years ago, and was for thirty years visiting physician to the Philadelphia Lying-in, Charity, and Nurses' Home.

Dr. JOHN H. B. AMICK died in Philadelphia on September 26 at the age of forty-two years. He was graduated in arts from the University of Pennsylvania in 1871, and from the medical department of the university in 1874. He had been a member of the Common Council and also a member of the State Board of Medical Examiners.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

SCIENCE AND RESEARCH—BRITISH ASSOCIATION—CANCER—SLEEPING SICKNESS—BRUSSELS CONGRESS—LUNACY IN IRELAND—VETERINARY CONFERENCE—DEATH CERTIFICATION—SMALLPOX—OBITUARY, JESSOP, DODD, WALTON.

LONDON, September 11, 1903.

THE British Association for the Advancement of Science, to give the full title to the mother of several other societies, including the medical one, is now sitting at Southport. Professor Dewar is succeeded in the presidential chair by Sir Norman Lockyer whose spectroscopical and astronomical work is well known. But in his address delivered on Wednesday evening he did not discourse on any abstruse topic, though he has a special aptitude for expounding such in a popular way. As education is the topic of the time, and as the country is in a state of decadence for want of it, according to the prevailing pessimism of the moment, Sir Norman took the opportunity of pleading for the endowment of our universities. We have only 13 of them, he wailed, against the 22 of Germany and the 134 in the United States. The German government gives more money in one year to one of its universities than the British Parliament votes for our 13. The advent of science in the last century brought great gain to Britain, he said, because she had full possession of those gifts of nature which made her the chief producer and exporter of manufactured goods. But rapid transit and other applications of science have diminished her initial supremacy. Science, which above all things is cosmopolitan—"planetary, not national"—internationalizes all resources. The worst of it all is, he declared, that while our resources were being sapped, our statesmen and our universities were blind leaders of the blind and neglected our great asset, brain power—science for political shibboleths. What, then, is the remedy? We must, declared Sir Norman, organize the national brain power. Trade follows brain. Science must be organized. A British science league, guild, chamber, call it what you will, was his dream until he found he had been forestalled by the founders of the British Association, which is not only a scientific parliament, but has the machinery for influencing all new councils and committees dealing with the subject. It has a membership of 25,000, and no less than 70 affiliated societies. It ought soon to have half a million members. A six-penny subscription from each would produce £12,000 a year to begin with. But more money must be had to create new universities and endow the old ones and promote research. "How is this money to be raised? I reply without hesitation," said the president, "duplicate the Navy Bill of 1888–9; do at once for brain power what we did there for sea power. Let £24,000,000 be set apart from one asset, our national wealth, to increase the other, brain power." This is rather a heavy demand even for the purse of John Bull, and I shall not be at all surprised if that generous old gentleman turns a deaf ear to the protestations of Sir N. Lockyer and the educationists that it would be a paying investment, and is a mere ½-thousandth part of his accumulated capital. He may even, perhaps, remind them that he was cajoled into sanctioning the education rate by solemn promises that it would never exceed three pence, and yet it has reached five times that amount, and is likely to be double that within a short time. From board schools to universities alike the demand is for more teachers at higher salaries.

Mr. W. Waldorf Astor has sent a donation of £20,000 to the Cancer Research Fund in response to the appeal made by Mr. Balfour who presided at the annual meeting in the unavoidable absence of the Prince of Wales. At the meeting in question Mr. Balfour uttered a wholesome warning against expecting immediate results. This was gratifying to earnest workers, inasmuch as many foolish statements have been circulated by the newsapers—such as that we are on the eve of a great discovery as to the cause and perhaps the cure of the disease. It seems unfortunate, to say the least, that influential papers should encourage such anticipations. The public has responded to the appeal for funds for scientific research, and it is particularly desirable that impatience for results should not be called forth, as it could only bring discouragement and check contributions.

The committee of the fund are not disposed to restrict the scope of the investigation in any direction, as is shown by the fact mentioned by Sir Wm. Church that they propose to engage in cattle breeding in a small way with a view to deciding whether the malignant diseases met with in animals are transmissible. The term cancer will be taken to include all malignant neoplasms, whether in man or animals, and whatever the variety or degree of

malignancy. The first report mentions that a great number of specimens have been submitted for examination, among them true epitheliomata from the horse, cow, and dog. Some specimens from the dog presented the histological characters of rodent ulcer. As to this disease the report supports the general opinion that many of the cases even of long standing are amenable to treatment by the *x*-rays. Perhaps here it should be said that many doubt whether it is to the "*x*-rays alone" that the effects of exposure to the focus-tube should be attributed.

The widespread interest in cancer is producing the usual crop of silly suggestions in the newspapers. Perhaps the editors are on their holidays and have left incompetent substitutes, though that cannot account for it altogether, since able editors commonly commit egregious blunders on medical matters. One of them has just circulated that treacle is a cure for cancer. Another class that loves to dabble in physic is the clergy. One of them who describes himself as having been a parson for three-quarters of a century writes to recommend that cancer cases should be made the subject of systematic inquiry by clergymen (of course!), doctors, boards of guardians, and others. No doubt this venerable parson would be willing to serve on the Research Fund Committee.

"If England were as energetic as the United States, then 80 per cent. of the malaria existing in her colonies would be stamped out." So said Major Ronald Ross in bidding good speed to the Congo expedition for investigating sleeping sickness. As an example of United States energy, Major Ross selected the measures taken so successfully in Havana to combat yellow fever, and the share taken in the campaign against the mosquito and the researches as to the yellow-fever parasite.

Speaking of mosquitos, I am reminded that Dr. Schoo has reported that there are some localities in India in which the insects appear to be immune to the malarial parasite. He conjectures the immunity may be caused by feeding on acid fruits. This accords with Professor Celli's observation that in a certain Italian immune area the mosquitos fed largely on tomatoes.

Colonel Bruce, R.A.M.C., and Dr. Nabarro of the Uganda expedition for investigating sleeping sickness are reported to have reached Mombasa on their way home, and to have declared that the ravages of the disease are unabated. These gentlemen, you will remember, went out in February last on behalf of the Royal Society and the Government to study the disease, and information has reached me that they favor the view that the trypanosoma is the parasite, and that it is carried by the tsetse fly.

Prof. Sims Woodhead is the delegate of the British Government at the Brussels Congress of Hygiene, and presided at the discussion on tuberculosis. He pointed out to the members, who were much divided in opinion, that a majority vote could in no wise settle a scientific controversy, and urged that they should not pass any except practical resolutions. Eventually, a large majority "*Resolved*, That human tuberculosis is perfectly transmissible from one person to another. Nevertheless, in the present state of our knowledge, it is necessary to recommend hygienic measures for the prevention of the propagation of animal tuberculosis to the human species."

There is an increase in the number of registered lunatics in Ireland, so noticeable that the inspectors announce their intention of investigating the Irish statistics and furnishing a special report to the Lord Lieutenant on the subject. In their fifty-second report, just issued, the total number on the first of January is given as 22,138, as against 21,630 on January 1, 1902. There is also a table in the report giving the proportion of the insane to 100,000 inhabitants from 1880 to 1902. In 1880 it was 250. In 1890, 344. In 1902, with a decrease of population, the proportion reached 499.

The National Veterinary Association opened its conference on Wednesday, and papers were read on "Anthrax and the Relation of the Veterinary Profession to Municipal Life." The president, Mr. Garnett, endorsed the cry for a health minister. Professor McFadyean was elected a V.P.

According to some, the doctor is always to blame. I told you a fortnight ago how one had been censured by a judge for giving a certificate of death without more evidence, and told he could have left it to the coroner. Now, we have the other side. At the conclusion of several inquests the coroner mentioned as a circumstance to make public that the death of a child had been reported to his officer who, on going to make inquiries, found the child alive. Application had been made at the hospital for a certificate and the case referred to the coroner. A juror at once said there had been great carelessness, and the doctor ought to have made inquiry before reporting to the coroner! Imagine the house surgeons wandering over the metropolis to relieve the coroner's officers of their proper duties! It is an apt illustration of the public's notion of the duties of doctors.

Lord Stanley has agreed to serve on the House Committee of the London Hospital.

Cambridge is not quite clear of smallpox yet. On the 2d inst. the M. O. H. reported 28 cases in the town, 8 in the country district, and 1 in a home. There are now under treatment 29, and 13 have been discharged in the week. At Lincoln 4 cases were discovered in a lodging house and removed to the Isolation Hospital. It is supposed the disease was brought in by a tramp. At Birmingham the Isolation Hospital was unoccupied for a week, and it was hoped that the outbreak was over, but a fresh case was admitted on Sunday. There was an outbreak in one district of Ealing, but it was strictly localized, all cases being at once isolated. The Local Government Board has appointed a committee to inquire and report on the remuneration, costs, and expenses of public vaccinators and vaccination officers, and whether any alterations should be made.

Another surgical veteran has fallen—T. R. Jessop, J.P., consulting surgeon to Leeds Infirmary, and late vice-president of the Royal College of Surgeons and Bradshaw lecturer, 1901. He took the membership of the college in 1859 and the fellowship in 1868. He presided over the surgical section of the British Medical Association at the Leeds meeting (1889) and gave an address on Cancer of the Rectum. He contributed various surgical papers and cases to the societies and journals, among which I may name those on the after-treatment in operations on the urinary organs, a case of extrauterine gestation with recovery of mother and child (Obst. trans. 1877.) Mr. Jessop's health began to fail some months ago. The end came from cerebral hemorrhage. He was in his sixty-sixth year.

Dr. T. Anthony Dodd of Newcastle-on-Tyne met with his death on Tuesday from injuries received by being thrown from his horse through the animal being frightened at a traction engine.

Dr. Luis Walton of New York, who was on a visit here, died suddenly on Wednesday in the Bath Club. At the inquest the verdict was heart failure.

It is sad to report the suicide of Dr. A. G. Merson of Walsall at the age of fifty-two years.

---

## OUR BERLIN LETTER.

(From Our Special Correspondent.)

BERLIN CLIMATE—WHEN TO OPERATE IN CASES OF APPENDICITIS—POST-EMBOLIC GANGRENE—PROFESSIONAL SECRECY—SCHOOL DOCTORS—EYE DISEASES AT THE BERLIN SCHOOLS—PROFESSOR FREUND'S ANNIVERSARY—THE KAISER AND THE MEDICAL PROFESSION.

BERLIN, September 5, 1903.

BERLIN has been suffering this week under an unusual heat, the temperature being 92° Fahr. in the shade. It would seem that Berlin's climate must be undergoing some change, as in late years the summers have been rainy and the winters mild, the reverse of what prevailed some six years ago. Metereologists explain this as the effect of some shifting of the Gulf current, the warm water penetrating into the North Sea.

During August the medical societies had no meeting. The medical section of the "Schlesische Gesellschaft für vaterländische Cultur" held a meeting the latter part of July. An interesting discussion took place on Dr. Tietze's paper, entitled "When Is it Necessary to Operate in Cases of Acute Appendicitis?" Dr. Sandberg pointed out that all retrocæcal abscesses have to be treated surgically because of the danger of thrombophlebitis and danger of paranephritic and subphrenic abscesses through infection of the retroperitoneal tissue. In cases of intraperitoneal abscess the indications are given by the symptoms. If the tension of the abdominal muscles, together with the pain and vomitings continue, if the fever remains high as well as the pulse (above 120 a minute), and if there is hyperleucocytosis (beyond 20,000), then the operation is necessary. Dr. Peiser called attention to Professor Sonnenburg's anatomical diagnosis. According to him, three well-known forms of appendicitis exist, appendicitis, simplex, a perforativa, and a gangrænosa. The simple form rarely demands an operation, except when a perforation suddenly occurs. The perforative form is of a more dangerous character, and an operation is always necessary when the pulse remains high while the temperature falls, or when severe pain still exists; a most characteristic symptom is this extreme pain, specially localized in the iliocæcal region. In such cases an operation ought to be performed within twenty-four hours.

Dr. v. Miculicz of Breslau said that he rarely operated

in the acute stage, as during the intervals the operation was more successful. In his clinic 104 cases of appendicitis were operated upon during the interval with no death. At the same time sixty-four cases of uncomplicated appendicitis were also operated upon without a death. In twenty-four cases appendicitis was complicated, and only four of these could be saved. In three cases the operation was performed too late.

At the monthly meeting of the Berlin Surgical Society Dr. Muehsam demonstrated a case of gangrene of both legs. The patient was suffering from heart disease, and as a result of embolism of the iliac artery gangrene of both legs had occurred and had made amputation of both legs necessary. Professor Sonnenburg reported a case of ileus postoperativus. He had seen ileus in three cases of appendicitis gangrænosa when it had happened through strangulation, in two cases of fistula of the bowels, and in one case of appendicitis without gangrene when atony of the intestines had taken place. The cæcum was principally affected. The diagnosis between ileus and pertonitis was reached through a leucocyte count, an increase beyond 15,000 indicating an abscess. Dr. Koerte thought that in all cases of ileus postoperativus infection had occurred.

An interesting legal decision regarding professional secrets has lately been rendered in Berlin. In a divorce suit the plaintiff wished to examine the physician who had treated her husband before marriage. The doctor refused to give evidence, as it was forbidden by law for practitioners to reveal a professional secret. The plaintiff applied to the court to force the physician to testify. But the court refused, saying that the physician would expose himself to punishment under the law if he revealed any secret whatever obtained in the course of his practice.

It is not long since in Germany a new department of public employment has been opened to the doctor. In twenty-two large towns of Germany medical school inspectors have been created, and in Berlin there are seventeen for the public schools, which are under control of the Berlin local government. The duty of these inspectors is to watch the sanitary institutions of the schools, to examine the children when entering the school, and to institute immediately suitable measures when an outbreak of infectious disease occurs, and also to give advice when the boys leave school, if they are fit for the profession they are going to choose. Not content with these school doctors, Dr. Hermann Cohn of Breslau is trying to convince the public and the local authorities that eye specialists also should be attached to the schools. No doubt the matter is of grave importance, as no organ of the human body suffers more at school than the eye, on which constant strain is put. Of 211,347 children in the Berlin schools, 5.5 per cent., *i.e.* 11,600, have been found to be suffering from defective vision. At Breslau, according to Dr. Cohn's statistics, of 52,159 school children 10 per cent. were affected; in the lower classes the number of eye diseases was 8 per cent.; in the highest classes it amounted to 35 per cent.

Two well-known members of the medical profession have recently celebrated anniversaries, Professor von Leyden and Professor Freund. The first celebrated the fiftieth anniversary of the obtaining of his medical degree, which was granted again by the medical faculty of Berlin. Professor Freund celebrated his seventieth birthday; he is ex-professor of gynecology at Strassburg, and is living now in Berlin. His standard work, "Gynäkologische Klinik" appeared in 1885, contributors to which were his assistants, Dr. H. Bayer and A. Homburger. Two of his latest papers on anomalies of the thorax, as affording a predisposition to tuberculosis of the lungs, are of special interest. He has also published several pamphlets of a more general character, on the emancipation of woman, and on the suitability of women to enter the medical profession.

The Kaiser has honored Professor von Behring with the title of "Excellenz," a title which is very rarely conferred on medical men, and up to now has been given only to eminent surgeons, as to Professor von Bergmann of Berlin, and lately to Professor Czerny of Heidelberg.

## PROTECTION TO THE EXAMINER IN CASES OF DIPHTHERIA.

To the Editor of the Medical Record:

Sir: The protection of the physician's own mouth and throat and nostrils during the examination of cases of diphtheria is a matter of quite serious importance. If the patient coughs, or even speaks, during the process, the spray projected into the face of the examining physician is almost sure to contain diphtheria bacilli, as may be shown experimentally by exposing culture material within a foot or so of the mouth of such a patient, and subjecting it to the ordinary processes of examination. The physician thus infected may be immune, and not develope a sore throat, but the bacillus will continue to live in the mouth of such a well person for a variable length of time, and may unconsciously be conveyed to patients in the same manner in which it was received during processes of examination. It would seem that special care should be taken to interpose something between physician and patient during such examinations so as to prevent this. The writer's own practice is to keep at hand a roll of ordinary aseptic gauze, thirty-two inches wide, from which a piece about a foot long may be cut. This folded lengthwise makes a double thickness about six inches wide, and long enough to tie across the bridge of the nose, extending down over the chin, the knot being at the nape of the neck. This leaves both hands free, and is a very effectual protection, the gauze being burned as soon as used, and the face and hands moistened at once with bichloride solution.

M. A. Veeder, M.D.

Lyons, N. Y., September 18, 1903.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, September 24, 1903.*

**A Note on the Association of a Rise in Systolic Blood Pressure with the Onset of Perforative Peritonitis in Typhoid Fever.**—John Bradford Briggs concludes from his study of the subject: (1) That patients with general or rapidly spreading peritonitis have constantly, at least in the early period, abnormally high blood-pressure. (2) That in perforative peritonitis sharp rise in blood-pressure may precede the onset of other symptoms. (3) That in doubtful cases in which perforative peritonitis is suspected, and the general previous blood-pressure level is known, the course of the blood-pressure after the onset of grave symptoms should receive consideration in determining the propriety of an operation.

**Three Cases of Tumor of the Cerebellum.**—John Jenks Thomas presents this paper. In two of the cases reported the symptoms were very indefinite, and in the first case for a long time it was impossible to say more than that we had to do with an intracranial new growth, as none of the characteristic symptoms of cerebellar tumor were present, unless ptosis, which appeared three days before death, can be so regarded. The second case cannot be considered to throw any light upon the chance of success of operation in these cases, as the operation was done in extremis. Still it may not be without advantage to note that in this case the tumor was a glioma of the cerebellum, and yet one that was sharply defined and that could have been easily removed by an early operation if it had been in a more accessible part of the cerebellum. The entire duration of the disease from the first onset of the symptoms was in this case only about fifteen weeks. In two of the cases there was a curious intermission in the symptoms—in the first case for a period of about six weeks, and in the other for a still longer time, though in this case the more troubleome symptoms, the ataxia, and difficulty in walking did not change materially during the course of the disease. As to the knee-jerks, in the first case they were lively, and there was a front tap contraction when the case was first seen, and the knee-jerks remained the same until far along in the course of the disease, when the left one became diminished. In the second case the knee-jerks were persistently absent. In the third case the knee-jerks were increased and there was double ankleclonus and Babinski's sign was present, which the writer considers to be evidence of pressure upon the motor tracts from increased fluid in the cerebral ventricles.

*Journal of the American Medical Association, Sept. 26, 1903.*

**Paraffin Injected Subcutaneously for the Correction of Nasal and Other Deformities.**—Harmon Smith describes his own experience, first on the cadaver and later on the living patient, and figures the apparatus he has found useful. Clinical indications are saddleback noses, depressed scars from mastoid and frontal sinus operations, scars following traumatism and smallpox pits. Dangers are abscess of slough, embolism, and deformity from over-injection. Causes of sloughing are lack of asepsis, excess of pressure, cutting off blood supply, injection into the skin instead of under it, and a constitutional diathesis as Bright's or diabetes. It is possible to use the method to overcome urinary incontinence, to diminish the size of hernial openings, to replace testes, cover stumps of amputated bones in order to prevent wear through flaps, to prevent adhesions in ankylosed joints after first breaking them up, to form plates in trephined skulls presenting dural adhesions, and to fill in malformations around the neck and in attenuated mammæ.

**Multiple Periosteal Sarcomata of the Cranium.**—W. L. Bierring gives the history of a case of this nature, his patient being a girl of five years, whose illness, beginning with anæmia, slight fever, and general malaise, lasted three months. Autopsy findings are slated in full detail. The case offers an illustration of the relationship between changes in hæmolymph nodes and the severe anæmias. According to Warthin, there is a certain amount of normal hæmolysis taking place in these glands, and the hæmolysis of severe or pernicious anæmia differs from the normal only in degree. As the last-named condition is probably due to some circulating poison, the nature of which is as yet unknown, so in the case described it is a circulating sarcoma process, which by reason of its involvement of the hæmolymph nodes led to an increased hæmolysis in these structures. The author believes that it is in this class of sarcoma-like tumors, including chloroma and those of lymphosarcoma and pseudoleukæmic type that a parasitic cause will probably ultimately be discovered.

*Medical News, September 26, 1903.*

**Nourishment, Medication, Hydrotherapy, and General Management of Typhoid Fever Cases.**—W. T. Baker believes that something must be selected which patients can and will eat. The patient must be kept well nourished. He then mentions buttermilk, almost any kind of meat soups, rice, oatmeal, wheatlet, toasted baker's bread in form of toast, with butter or milk or hot water, or the patient may eat it dry from the oven, chewing it well and taking plenty of water at the time; young chicken, rabbit, or bird made with soup; preserves, jelly, the syrup and softer parts of canned fruits; a baked apple, a well-ripe tomato, a baked Irish potato. At first, he gives the mild chloride of mercury with bicarbonate of soda. For high fever and aching, codeine, phenacetine, salol and quinine are given. As an antiseptic, carbolic acid, tincture of iodine, and water are combined. He suggests the careful study of the use of acetozone as an intestinal antiseptic. Hydrotherapy is a most important part of the treatment. Sponges, plunges, and packs are valuable. A good nurse is a necessity. Care of the excretions should be taken. The patient must be kept cheerful. The writer concludes with a report of cases.

**Concerning Some Points in the Treatment of Typhoid Fever.**—Glentworth R. Butler discusses diet, the use of cold, and the employment of drugs in relation to typhoid fever. He considers milk as the best article for the basis of a typhoid fever diet. Its administration can be much varied. We may give milk and mineral waters, buttermilk, koumys, oyster and clam soup with milk, hot milk flavored with a little strong, black coffee, cold milk, and many other forms. In every case, if the person is used to drinking coffee, tea, or cocoa, these are allowed once or twice daily. Various meat broths, as mutton, beef, and chicken, are given in moderation, unless the bowels are moving too freely. Albumen water acidulated with lemon juice is often useful. Plain ice-cream, water ices, and jellies are, as a rule, unobjectionable. Water should be given as regularly as food. The writer commends the following methods in the application of cold: cold mitten rub, towel bath of Baruch, and the ice rub. Flies must be carefully kept from the patient. Probably most cases of typhoid fever are overmedicated. The ordinary putrefactive and fermentative changes in the intestinal tube can be favorably modified by antiseptics. Among these eligible drugs are salol, guaiacol carbonate, creosote carbonate, zinc or sodium sulphocarbonate bismuth, and turpentine. An initial dose of calomel is desirable. In the medical treatment of intestinal hemorrhage, calcium chloride and gelatin are of value; also moderate doses of opium or its alkaloids to quiet the restlessness and to sustain and regulate the action of the heart.

**The Pathology and Treatment of Tardy Postoperative Intestinal Obstruction.**—Ellsworth Eliot says that acute obstruction following laparotomy is not a rare occurrence. In the cases of "tardy" obstruction, the cause is always of a mechanical nature, the lumen of the intestine being narrowed by the contraction of a circumferential cicatrix within its wall or by the constriction of a band without, beneath which the intestine has accidentally passed and subsequent extrication has proved impossible. In other cases the stricture is due to the progressive kinking of a segment of intestine from the contraction of adhesions of organized connective tissue, joining together at one angle those loops of which the segment is composed. In many cases several of these conditions coexist. Stricture due to the constriction of a circumferential scar in the wall of the intestine is of the simple non-malignant variety and presents the usual features of that condition. At the time of laparotomy, there should be careful exclusion of any kind of mechanical, thermal, or chemical irritation from the contents of the abdomen. Ligatures should not be needlessly applied. All stumps should be covered, prior to the closure of the abdomen, with a smooth peritoneal investment. As to drainage, as small an amount of drainage material should be used as is consistent with the patient's safety, and in the event of a capillary gauze drain, by enveloping the same in a cylinder or sheath of sterilized rubber tissue. The drain should be changed early. The position of the patient should be changed often. During the first twenty-four hours, rectal enemas of warm saline solution are valuable. In cases of persistent vomiting, lavage is used.

*New York Medical Journal, September 26, 1903.*

**The Gastric Contents in Gastroptosis.**—T. R. Brown has conducted a series of tests in cases classified according to the severity of symptoms and the amount of stomach displacement and dilatation. His findings in general are that gastroptosis *per se* leads to a very slight diminution of the free hydrochloric acid, and it is the subsequent dilatation which so often complicates gastroptosis that leads to the marked diminution of free hydrochloric acid the diminution apparently being more marked the greater the associated dilatation.

**Some Obscure Cases of Eye Strain.**—The detailed histories of three cases are given by S. W. Marlow. They illustrate first, that the most careful investigation and the apparently accurate correction of all discoverable visual errors may completely fail to relieve symptoms; may, in fact, aggravate them, and yet the symptoms may still be due to eye strain. Indeed, the fact that glasses which are apparently correct aggravate the symptomsis, he believes, in most cases evidence that the latter do arise from eye strain, and that a latent error is present, usually an error in the muscle balance. In the second place, he believes that lapse of time is a very important factor in the elucidation of the true nature of these cases. The action of the accommodation in neutralizing refractive errors is so automatic and persistent that all efforts to annul it sometimes fail to be completely effective, even atropine and other powerful cycloplegics failing to bring about a complete relaxation. The natural relaxation due to advancing years often reveals a hitherto latent error. Similarly the instinctive tendency to see single and not double causes the extrinsic muscles to contract so as to maintain a parallelism of the visual lines. This contraction is so constantly maintained that the muscles get into a condition of tonic spasm, which is extremely persistent. Just as we have a spasm of the accommodation in cases of hyperopia and astigmatism in the interest of clear vision, so we have a spasm of the extrinsic muscles in the interest of single vision, and the latter is far more difficult to demonstrate than the former. He has seen cases in which the lapse of time alone has revealed the true nature of the ocular condition, and occasionally old age is reached before the condition becomes manifest.

*American Medicine, September 19, 1903.*

**The Bacillus of Syphilis.**—Justin De Lisle presents the following conclusions: This microbe is found in all patients during the secondary manifestations of syphilis. This microbe is agglutinated or clumped by the serum of individuals of secondary syphilis, but no reaction takes place with the serum of healthy subjects. This microbe can be grown after having passed through a porcelain filter. The direct inoculation of animals with the blood of syphilitics during the secondary manifestations causes the production of a hard ulcer, involvement of the lymphatic glands, paraplegia, etc. Inoculations of the laboratory animals with cultures of this microbe occasion special lesions comparable to those observed in syphilitics. It combines with the special sensitizing body (sensibilitrice) generated in the organism of animals vaccinated with syphilitic products. Cultures of this bacillus are without effect when inoculated into syphilitics. Like syphilis in man, this microbe dies with the infected animal.

**The Treatment of Chronic Round Ulcer of the Stomach.**—Frank H. Murdock states that in his own series of thirty-two cases, the average duration of this malady was four years and nine months. The first question to decide is that of rest in bed. Women, almost without exception, require this, while men do not. Manual laborers may, as a rule, pursue their ordinary work, and make good recoveries without loss of time, while brain workers must be relieved of all mental work and worry, at least during the early months of treatment. If free hydrochloric acid is found present in normal or excessive quantities, milk will form the principal article of food. Beef juice is also of great value, especially in anæmic cases. If free hydrochloric acid is absent, or if there is achylia, milk is not indicated, and in these cases white of egg in water, beef juice diluted with barley water, rice, vegetable or barley soup, strained, leben, and buttermilk will usually agree well. Buttermilk is easily prepared from

sweet milk by setting it aside for twenty-four or thirty-six hours until it thickens, when it is beaten for five minutes with an egg-beater or with a machine for making whipped cream. The two drugs most commonly used are bismuth and silver nitrate. As a laxative, Carlsbad water or Carlsbad salts are often used. It is not safe to begin the administration of solid food till the epigastric tenderness has disappeared. The most serious complications met in chronic gastric ulcer are hemorrhage and perforation. In all cases of hematemesis absolute rest in bed should be insisted upon, and nothing should be given by mouth but small pieces of ice. An ice-bag should be placed on the epigastrium, and nourishment should be given by the bowel. Other remedies may be tried. When perforation occurs laparotomy should be performed as soon as the diagnosis is made.

*American Medicine, September* 26, 1903.

**Progressive Funnel Chest.**—J. L. Tracy describes a deformity which he has seen in several members of the same family. The ensiform cartilage has retracted toward the spinal column for at least three inches, making a cup-like depression that deep and about four inches in diameter. The heart is a little displaced to the left, the stomach crowded downward, and the liver seemingly is forced up under the false ribs. The trouble is progressive. In the patient's child, now two years old, the depression shows only as a dimple. In his father, aged seventy-nine years, the depression reached nearly to the vertebras. His brother and his grandfather showed the same deformity.

**Personal Experience in Operations upon Diabetic Patients.**—Charles P. Noble has operated upon seven women suffering from diabetes mellitus. Of these seven, six made good recoveries and one died in diabetic coma. In the six remaining cases the healing of the wounds and the general progress of the patients toward recovery were not different from that in patients not the subject of glycosuria. A careful reading of the reported cases would indicate that the proportion of deaths from other causes than coma was not extremely high. The chief cause of death after operations upon diabetics is coma, and apparently this result is the one which is the least possible to guard against. The rule which the writer has followed has been to postpone operation if more than 2 per cent. of sugar is present in a total excretion of three pints a day. In all cases preliminary treatment by diet and the administration of codeine and strychnine has been followed. After operation morphine, codeine, and strychnine have been administered. Salt solution has been freely given per rectum and by hypodermoclysis, and the diet has been strictly regulated. The counterindication to operation is strongest in those patients suffering markedly from the constitutional symptoms of diabetes—poor nutrition, wasting, intense thirst, and morbid appetite

**Spotted Fever (Tick Fever) of the Rocky Mountains.**—John F. Anderson suggests "tick fever" as a name for this disease, on account of the relation of the tick to the spread of the disease, and the fact that there are already two diseases of man, sometimes known as "spotted fever." This disease has prevailed in the Bitter Root Valley for a number of years. Cases occur exclusively in the spring and early summer. Persons from fifteen to fifty years of age more often contract the disease, on account of being more actively engaged in out-door work. The parasite found in the red blood corpuscles of persons suffering from tick fever resembles in a way both the parasite of malaria and Texas cattle fever, but it is not pigmented, but like them it is amœboid. The parasites are never found in very large numbers. The work done on this subject would suggest strongly the belief that the ticks are necessary for the transmission of the disease, but the actual fact cannot be proved scientifically until carefully controlled experiments are made on non-immune persons. Incubation takes from three to ten days. For a few days the patient may have chilly sensations, malaise and nausea, finally there is a distinct chill and the person takes to bed. There is some pain in the back and head, soreness of the muscles and bones, constipated bowels and congested conjunctivas. The pulse is out of all proportion to the temperature, usually running from 110 to 140. There is a progressive decrease in red cells. An eruption appears, usually on the third day. The mortality varies from year to year, some years as many as 90 per cent. of those attacked dying. Death usually occurs between the sixth and twelfth day. Until the past season the treatment of the disease has been purely symptomatic, but since the discovery of the parasite quinine has been given in large doses. As soon as a person is bitten by a tick the insect should be removed and the place cauterized with 95 per cent. carbolic acid.

*The Lancet, September* 19, 1903.

**Tapeworm as a Cause of Chorea.**—J. A. W. Pareira publishes details of the case of a girl of six years who was passing segments of tapeworm, and in whom, two or three weeks later, choreic manifestations appeared. When he first saw her she was in the second grade, or the severe form of the disease, in which the movemens were general, and she could not talk. There was never any suspicion of rheumatism in the case, and her heart remained normal throughout. A dose of filix mas dislodged the parasite, and in a month's time the child was practically well. The tapeworm was, in the author's opinion, the direct exciting cause of the chorea.

**Four Cases of Blackwater Fever.**—These are reported by J. C. Taylor, and are noteworthy for the following reasons: (1) All these cases developed on board ship homeward bound from the west coast of Africa, presumably away from any direct or recent infection. Only one of the cases had suffered from a previous attack. (2) In all the cases there had been a slight chill (malarial), for which one gram of quinine had been taken, and within a few hours the symptoms developed. (3) The last point is the satisfactory use of boric acid, one gram of which in hot water was given every two or three hours, according to the severity of the attack. If there is vomiting, it could be given by rectal or subcutaneous injection.

**A Case of Malignant Disease Following Splenic Anæmia.**—In the case of the patient of C. H. Sedgwick, a man of fifty-eight years, evidences of malignant disease of the abdomen gradually followed, and autopsy revealed deposits in the lungs, mediastinal glands, ribs, liver, spleen, and inguinal glands. No definite conclusion as to the exact nature of the growths could be arrived at, but it was, in all probability, carcinomatous. The author thinks that the malignant disease, wherever the primary focus lay, was not the primary cause of the illness, but that it supervened on splenic anæmia. Another point, which touches on some recent observations on the causation of malignant disease and its relation to arsenical administration, is the fact that the patient for some years previously had been treated with arsenic for psoriasis and with a very considerable amount of relief.

**The Occurrence and Significance of Cutaneous Hyperæsthesia in Appendicitis.**—James Sherren offers the following conclusions: (1) Cutaneous hyperalgesia is probably present at some time during all first attacks of appendicitis, except, perhaps, in the fulminating type, and depends upon tension within the appendix. (2) It may be absent in attacks after the first, if the first attack was of sufficient severity to destroy nerve tissue in the wall of the appendix. (3) When present in attacks subsequent to the first it often persists long after all other signs of the disease have gone, owing to the tension within the appendix being kept up by the presence of a stricture. (4) It gradually disappears during convalescence as the other signs of the disease clear up. (5) Disappearance of cutaneous hyperalgesia without improvement in the general condition of the patient is a sign of perforation or gangrene of the appendix, and should be a signal for immediate operation. (6) The presence of cutaneous hyperalgesia is no contraindication to operation. Abscesses may form and general peritonitis may develop while it is present. (7) Its absence, on the other hand, is of great importance. Absence of cutaneous hyperalgesia, the patient coming under observation early in the first attack of appendicitis, is a sign of gangrene of the appendix unless the case is obviously a mild one and the patient is rapidly getting well. (8) Cutaneous hyperalgesia is, as a rule, absent in cases of abscess of the appendix. (9) The age of the patient and the position of the appendix have no influence upon the cutaneous hyperalgesia. (10) It is occasionally of use as an aid to the diagnosis of appendicitis.

*Münchener medicinische Wochenschrift, September* 8, 1903.

**Tuberculous Infection through the Intestine.**—L. Sorger tried in vain to produce tuberculosis in a fox by feeding the animal for more than six months with material contaminated with tubercle bacilli. No intestinal lesions were produced and the general condition of the animal remained good. This animal is hence to be regarded as immune to the human tubercle bacillus. The author suggests that this natural immunity of the fox may account for the apparent usefulness in the treatment of pulmonary tuberculosis of some of the old preparations, which contained as one of the ingredients certain portions of these animals.

**Influence of Concentration of the Urine upon Tests for Albumin.**—Benno Hallauer shows that the tests for albumin are very deceptive and often fail to give a reaction in markedly concentrated urines which contain albumin. For this reason all concentrated urines should be properly

diluted before the tests are applied. In concentrated urines the acetic acid—ferrocyanide test is most inaccurate, failing to give a reaction when the urine is reduced one-half in volume. The heat and nitric acid test is better, giving usually a reaction until the urine is reduced to one-quarter of its volume. Under the like conditions Heller's test is variable, frequently giving a reaction, but as often failing to do so.

**Does Sugar Metabolism Entirely Cease after Extirpation of the Pancreas.**—Hugo Luthje, by a special process, entirely removed the pancreas in a series of dogs. That the pancreas was entirely removed was demonstrated by the subsequent autopsy findings. These animals were then starved and sugar appeared in the urine until a certain degree of emaciation was reached, when it entirely ceased. If now the dogs were fed upon albuminous matter, the sugar in the urine again reappeared. From this it is probable that when the animal has used up its reserve albumin for its nutrition it appropriated the sugar in the system for nutritional purposes, and hence at this time it disappeared from the urine. When albuminous food was supplied the need for its so doing was at an end and the metabolism of sugar ceased, as evinced by its renewed presence in the urine.

*Berliner klinische Wochenschrift, September 7, 1903.*

**Origin and Properties of Alexins.**—R. Turro regards the alexins as chemical bodies which act upon bacterial protoplasm—the process being known as bacteriolysis. The alexin is a product of the cell protoplasm. It exerts its action when in solution in aqueous physiological salt solution. The properties of the various alexins vary, according to the character of the cell protoplasm which produces them. Hitherto alexins have been found in the thyroid gland, the suprarenal capsules, the kidneys, the lymph glands, the muscles, the liver, the spleen, the blood plasma, and finally in the yoke of the egg after previous solution of the albumin. From a chemical standpoint the alexins are to be regarded as enzymes which digest the bacteria by the means of a progressive hydrolysis. The resistance of an organism against infection (natural immunity) is dependent upon the physiological processes in the cell protoplasm which favor the solution of the alexins, and hence their action.

**"Oat Cure" in Severe Diabetes Mellitus.**—Carl von Noorden gives his further experiences with this treatment, which consists of the following exclusive diet: Daily quantity—oats 250 gr., butter 300 gr., albumin 100 gr. This is prepared in the form of a soup and given in equal quantities every two hours throughout the day. In addition there may be given a moderate amount of cognac, wine, and strong black coffee. When cases of severe diabetes are placed upon this diet one of four results may be expected. In no case can the outcome be prognosticated until ample trial of the diet has been made. (1) In a certain proportion of cases the general condition improves and the sugar disappears from the urine. Furthermore, this improvement remains permanent under a return to the usual diabetic diet and eventually to the diet of ordinary individuals, provided the transition from diet to diet is slowly carried out and carefully watched. (2) In a second class of cases the primary improvement takes place as above depicted, but is not maintained upon a removal of the "oat diet." (3) A third class, when placed upon this treatment, show a moderate improvement, but at no time does the sugar entirely disappear from the urine. (4) A fourth and final class show no improvement as the result of the "oat cure." It might be expected that the results in cases of severe diabetes would indicate that in moderate diabetes the "oat cure" would be uniformly effective. This is, however, not the case, since many of the latter class of cases do poorly when placed upon the treatment.

*Deutsche medicinische Wochenschrift, September 3, 1903.*

**Formation of Specific Antibodies in the Blood after Cutaneous Infection.**—F. Kasten confirms Hoffmann's results in that he has been able to produce specific agglutinins and bacteriolysins in the blood of rabbits, which he had submitted to cutaneous inunctions with various bacterial cultures. In different series of experiments there were used typhoid bacilli, cholera organisms, and staphylococci. Bacteriological examination of the blood of the animals thus treated, together with the autopsy findings, conclusively shows that no infection took place as the result of the inunctions, since the bacteria employed were never found within the bodies of the rabbits.

*French and Italian Journals.*

**The Pathogenesis of Uræmia.**—M. Casters from his researches concludes that uræmia should no longer be attributed exclusively to autointoxication from retention of urine. Changes in the internal secretion of the kidneys, as well as nephrotoxins and nephrolysins, should be taken into account as well. Although we are as yet unable to state even approximately just what part they play in the etiology of uræmia, it is not irrational to attribute to them a prominent rôle in certain cases in which the patient is attacked in apparently perfect health, without any previous warning, especially without anuria or oliguria.—*Archives Médicales Belges*, August, 1903.

**The Diagnostic Value of Tuberculin.**—Emilio Malfatti and Francesco Sarcinelli conclude from their experimentation that injections of tuberculin progressively increased up to one centigram are innocuous. The age of the subject has no influence on the reaction. A febrile reaction follows in forty-eight hours. In advanced cases of tuberculosis a large dose of tuberculin is needed to induce reaction, which is less marked than that obtained with a smaller dose in the earlier stages. On the whole, however, the results of injections of tuberculin do not justify a diagnosis of tuberculosis unless accompanied by other diagnostic signs.—*La Riforma Medica*, August 26, 1903.

**Symptoms Similar to Those Described by Dercum.**—Disma Cecchini reports the case of a woman suffering from pain in various parts of the body, followed by the formation of fatty deposits. Dercum's disease has been attributed to affection of the sympathetic, but the author discredits this theory, and holds that it should be classed as a general trophoneuroses, with a tendency to symmetrical neoformations in certain tissues. Variations in the nature of the pains do not lead to the conclusion that there are several types of the disease, but point to probable changes in the peripheric nerves, which may be of varying forms, while the fundamental morbid entity is the same.—*Gazzetta Medica di Roma*, August 15, 1903.

**Attempted Suicide by Means of Cultures of Eberth's Bacillus.**—Paul Duflocq and Roger Voisin report the case of a young woman in a hospital who, being in poor health and not happily married, so resented pregnancy that her desire was to attempt suicide. Another patient having died of typhoid fever, this young woman cleverly obtained information as to the disease and its cause, and swallowed the contents of two culture tubes of Eberth's bacillus. After a short period of incubation (ten days) she was taken with typhoid fever, which followed its usual course. The patient was given 176 cold baths in all. No abortion occurred, and she left the hospital in good condition, giving birth at term to a living child.—*Archives Générales de Médecine*, September 1, 1903.

*Annals of Surgery, September, 1903.*

**A Case of Ascites Due to Liver Cirrhosis, Treated by Operation.**—R. Morison reports the case, his patient being a man of fifty-two years. He had been treated by the usual methods of limitation of fluid ingesta, purgatives, and tapping. The operation is thus described: An incision about four inches long opened the abdomen between the ensiform cartilage and the umbilicus. The cut subperitoneal fat was vascular, and bled freely. A large amount of clear straw-colored fluid escaped as soon as the peritoneum was divided. A second opening was next made between the umbilicus and pubis, large enough to admit a half-inch diameter glass drainage tube, which passed through it into the pelvis. Some adhesion was present between the liver and the omentum and between the omentum and the abdominal wall. The liver was firm, finely granular on the surface, and of about normal size. The spleen was hard, and enlarged to at least double its normal size. The abdominal cavity was dried with sponges, special care being taken to rub the surface of the visceral peritoneum opposed to them. The omentum was fixed across the anterior abdominal wall by catgut sutures. The upper incision was entirely closed by catgut sutures. The lower was kept open for a drainage tube through which the fluid was pumped out of the pelvis. Over the dressings, broad, long strips of adhesive plaster were applied transversely from the chest above to the drainage tube opening below. This was for the purpose of keeping the upper part of the abdominal cavity empty of fluid and the parietal closely applied to the visceral peritoneum. The patient made a good recovery from the operation. Three weeks after his discharge from hospital, tapping was again necessary. From this time on the fluid gradually diminished, and three years and a half later he was reported as being very well. The history of the operation is reviewed and other reported cases referred to.

**Blood Examinations in Their Relation to Surgical Procedures.**—L. L. McArthur believes that much valuable information can be derived from examining (1) the hæmoglobin content, (2) leucocyte decrease, and (3) leucocyte increase—polymorphonuclear and mononuclear. With a hæmoglobin content of between 40 and 50 per

cent. we are treading on dangerous ground. With a content of below 30 per cent., operation must be avoided unless instantly imperative. We must distinguish between a temporary sudden hæmoglobinæmia, as in uterine hemorrhage, and the gradual form caused by such conditions as gastric ulcers, uterine fibroids, etc. He finds that leucocytes decrease (from the normal 6,500) with certain diseases (malaria, tuberculosis, measles) and most often in typhoid fever. This fact may help us in differential diagnosis, and one illustrative case is given in which the diagnosis was at first made, but the leucocyte count pointed unmistakably to suppuration, which was finally located in the liver. The author also notes that there are two principal forms of white cells, and that the number alone must not be depended on in doubtful cases, but the form and other peculiarities must be noted if all the knowledge to be gleaned is to be utilized. The multinuclear leucocyte is notoriously the one to wander out in the neighborhood of an infected area, and, dead or dying, to constitute the pus formed. What wonder, then, that with increased demand there comes an increased production; the difficulty as yet being to differentiate between the physiological waves of increase and those produced by other factors than infection. Cabot's investigations make a 33 per cent. increase quite within the normal for such changes as digestion, exercise, and other physiological processes may induce. Indeed, the number of causes which may lead to a mild leucocyte increase are so numerous that only when associated with positive clinical evidences of disease should such increase have any influence in the ultimate decision. Again, the absence of such increase should not outweigh clinical evidence sufficient to make a diagnosis, but may, with justice, influence prognosis and treatment.

**Operative Possibilities in Cases of Advanced Carcinoma of the Breast.**—L. S. Pilcher reviews his experience between the years 1888 and 1900 inclusive. His procedures were conducted in accordance with the teaching that the incisions through the overlying skin should go wide of apparent disease and that the breast and axillary lymphatics with the connective tissue and fat in which they were imbedded should be dissected out as one unbroken piece. Classes one and two include complete ablation to apex of axilla, both with and without removal of the pectoralis major muscle. Of the thirteen cases summarized, the later history of all but one being known, it appears that four have remained well to the present time, periods of from eight to ten years having elapsed since operation; that three more enjoyed a period of immunity lasting for six years, and then in each case developed renewed cancerous disease; that in three cases evidence of recurrence, in distant regions, showed themselves within three years after the operation, and that in but two cases did local recurrence take place. In class 3 ablation was accompanied with removal of both pectoral muscles and comprised twelve cases. In one case the later history is unknown; of the remaining eleven, one lived five and a quarter years free from recurrence and died of pneumonia at the age of seventy years. Two others are well at the present time, three years and three years and four months respectively after the operation. One is living five and a half years after operation, but with slowly advancing recurrence in axilla and above the clavicle. One other is still living three years after operation without external recurrence, but with evidence of carcinoma of liver. Six patients have died at periods varying from twelve months to five years and a half after operation. Class four embraced in addition to the procedures named, those cases in which the supraclavicular region was cleaned out. Of this number but two have remained well, viz., six and four and a half years since operation. One other still lives (two years and a half) in good general health, but with a beginning enlargement of the costochondral articulations on the affected side, which indicates recurrence in the ribs. The others all died, generally from intrathoracic metastasis. The author further states that present experience warrants the statement that surgery can promise a very large proportion of absolute cures to cases of cancer of the breast if its resources are employed as soon as the presence of the disease is determined, even though it be acknowledged that the disease is there already in an advanced stage.

**Myositis Ossificans Traumatica.**—A case of this nature is reported by J. F. Binnie, whose patient was a man of forty-one years who received, while boxing, a severe bruise on the right forearm and arm. A tumor gradually developed, which was removed, the wound healing by primary union. Six months later there has been no recurrence, and there was no disability. Microscopical examination revealed the fact that the mass was of the variety indicated in the title. The author discusses the various theories of causation of the condition and appends an extensive bibliography.

# Clinical Department.

## A CASE OF ABSCESS OF THE RIGHT CEREBELLAR HEMISPHERE WITH CARIES OF THE LEFT MASTOID PROCESS.*

By E. GRUENING, M.D.,
NEW YORK.

The case here described illustrates a difficulty encountered in the localization of an otitic brain abscess. Retardation of the pulse rate, drowsiness, vomiting, and rapidly developed optic neuritis were the symptoms pointing to the presence of cerebral abscess. As both ears were affected, the question arose as to whether the abscess was situated in the right or left side of the brain. At the time of admission the right ear was in a state of acute inflammation, which rapidly subsided after paracentesis of the drum. The left ear was more seriously affected. The mastoid cells were filled with pus and broken down bone tissue and one of the ossicles, the incus, was carious. For this reason the left temporosphenoidal lobe and the left cerebellar hemisphere were exposed and freely aspirated. The result of the operative exploration was negative. At the post-mortem examination a large abscess was found in the right cerebellar hemisphere.

B. S., a schoolgirl, ten years of age, was admitted to the Mount Sinai Hospital on April 3, 1903.

*Past history.*—In early infancy had measles, scarlet fever, and diphtheria, but no ear complications after these diseases.

*Present illness.*—Acute onset ten days ago, with pain on left side of the head which still persists. Five days ago had chills and fever, severe headache, and purulent discharge from left ear. Child has been drowsy since onset and has been vomiting nourishment for the past three days.

*Left ear.*—Drum head red and swollen. Small perforation in lower anterior quadrant. No discharge. Over the region of the mastoid the skin is red and swollen and pits on pressure. No fluctuation. Tenderness over pit, antrum, and behind the mastoid.

*Right ear.*—Drum is red and swollen. No perforation. Slight tenderness over tip and antrum of the mastoid.

General condition fair. Well nourished. Answers questions readily, but relapses into drowsiness when not spoken to. Tongue dry, heavily coated. Pupils of equal size, react well.

Ophthalmoscopic examination negative. Examination of the lungs, heart, liver, spleen, and abdomen was also negative. Temperature 102.8°. Pulse 108. Respiration 28. Several hours after admission, temperature 104.8°.

*Operation.*—Osteotomy for mastoiditis (left). Nitrous oxide and ether anæsthesia. Bilateral paracentesis of drum. Usual curvilinear incision over mastoid. Periosteum easily lifted. Cortex hard. Mastoid cells and antrum contain granulation tissue and pus. Thorough curettage. Sigmoid sinus exposed. It appears normal. Thorough irrigation. Dry iodoform packing. Dry dressing. Time 45 minutes.

April 4. Patient much improved. Temperature 101°. Pulse 104. Respiration 24. Profuse seropurulent discharge from right ear.

April 5. General condition good. Drowsiness has disappeared. Temperature 100.4°. Pulse 98. Respiration 24. Diminished mastoid tenderness on right side. Discharge from right ear still profuse.

April 7. Wet dressing to mastoid wound. Tem-

*Read before the American Otological Society at the Congress at Washington, May 12, 1903.

perature 99. Slight discharge from right ear. No mastoid tenderness.

April 10. No discharge from right ear. Mastoid wound granulating. Out of bed.

April 16. Temperature 99.4°. Pulse 88. Respiration 24. Wound healthy. Dry dressing.

April 20. Patient vomited. Temperature normal. Right ear does not discharge. No tenderness of right mastoid. Ophthalmoscopic examination negative.

April 21. Vomited repeatedly. Right pupil larger than left. Ophthalmoscopic examination negative. Temperature normal.

*Operation.*—Cleaning out of middle ear. Exposure of dura. Multiple exploratory puncture of brain with aspiration. Nitrous oxide and ether narcosis. Incision extended upward and forward. Superior and posterior walls of external auditory canal, the drumhead, the ossicles, the antral and tympanic roofs, the temporal ridge and a part of the squama were removed. Incus carious. The malleus sound. The dura was normal in appearance. Intracranial pressure not markedly increased. The aspirating needle was introduced into the temporosphenoidal lobe in all possible directions. No pus was found. Wound irrigated with alcohol and dressed dry.

April 22. General condition improved. No headache. Pupils equal. Temperature normal. No headache.

April 25. Temperature normal. Appetite good. Slight drowsiness.

April 26. Temperature normal. Wound covered with healthy granulations. Vomited at four in the afternoon and again at eight. Pulse retarded, 60–68. No headache. No aphasia.

April 27. Temperature normal. Pulse 64. No headache. Slight drowsiness. Ophthalmoscopic examination negative.

April 28. Pulse 66. Frontal headache. Drowsiness.

April 29. Continues to be drowsy. Vomited more. Pulse 60–70. Refuses food. Right pupil larger than left. No aphasia. No papillitis.

April 30. *Operation.*—Exploratory puncture of left temporosphenoidal lobe and left cerebellar hemisphere. Anæsthesia by nitrous oxide and ether. Wound curetted and flushed with alcohol. Upper knee of sigmoid sinus and lateral sinus laid bare. Removal of part of the parietal bone above the knee of the sigmoid sinus and part of the occipital bone below the lateral sinus, exposing a larger area of the temporosphenoidal lobe and of the cerebellar hemisphere. Numerous punctures and aspirations in all directions in temporosphenoidal lobe and cerebellum. Result negative.

May 1. No change in general condition. Remains drowsy. Pulse faster and irregular. Receives nutriment enemata.

May 2. No change.

May 3. Does not retain nutrient enema. General condition not changed.

May 4. Drowsy. Answers when aroused. Says she has no pain. Vomited.

May 5. More drowsy. Involuntary urination. Pupils equal and dilated. Ophthalmoscopic examination negative. General tonic convulsion lasting three minutes. Pupils widely dilated. Vomited after convulsion. Temperature 98.6°. Pulse 50–60. Respiration 16–18.

May 6. Child still can be roused but with great difficulty. Double optic neuritis present. Examination of right ear. Perforation healed. Temperature 97.4°. Pulse imperceptible. Respiration 8.

May 7. Tonic convulsion following enema. After convulsion respiration very slow, three per minute. Pulse can be felt. Artificial respiration kept up two hours.

*Operation* without anæsthesia. Multiple aspirations of left temporosphenoidal lobe and left cerebellar hemisphere, with negative result. Artificial respiration kept up during operation. Child died at 5.35 P.M. Wound inspection and partial autopsy allowed.

*Report of the Pathologist.*—Left mastoid region, site of recent operation found clean. Granulations beginning to form. Dura mater, as far as could be seen, appeared normal. Cerebrum normal on surface and in sections. Recent aspirations in all directions negative. Cerebellum, external inspection, negative on palpation; no softened spot or bulging. Vermiform process negative.

On section, left hemisphere shows sites of recent aspirations. No hemorrhage or abscess. In the right hemisphere near upper surface of lobus clivi, and extending forward and backward, was an abscess cavity the size of a walnut filled with grayish red pus. No odor. Surrounded by a pyogenic membrane of the same color. The external layers of the membrane were fibrinous in character. The surrounding brain tissue is negative in appearance. Culture from abscess. Streptococcus.

In the hardened specimen the abscess cavity measured 3 cm. in the antero-posterior, and 18 mm. in the transverse diameter. The limiting membrane had a thickness of 2.5 mm.

36 East Fifty-seventh Street.

## SYPHILITIC PHARYNGEAL ABSCESS, WITH NECROSIS OF A CERVICAL VERTEBRA.

By NATHAN G. WARD, M.D.,
PHILADELPHIA,
OTOLOGIST AND LARYNGOLOGIST TO ST. AGNES' HOSPITAL.

Syphilis of the upper respiratory tract may occur during any of the three clinical stages, or as hereditary manifestations. The lesions are inflammatory, with or without ulceration, or there may be extensive necrosis involving the bone and accessory sinuses. The most destructive lesions are to be found in the tertiary stage or in hereditary cases. G. Hunter Mackenzie considers the latter the worst and most intractable.

Postpharyngeal abscess with necrosis of a cervical vertebra, caused by syphilis, is rare, and to the few reported cases I add the following:

W. M., age forty-nine. About three weeks after her last confinement, which was twelve years ago, the first manifestations appeared on the genitals, the nature of which could not be ascertained. Six years later she had an erythematous, papular, and vesicular eruption, appearing on the neck and chest and spreading over the entire body. Under treatment the skin manifestations disappeared and she was free from all trouble for some time, but as to how long I could not definitely learn. Then followed in succession: ulcerations on the anterior and lateral surfaces of both legs below the knee, one over the left malar bone, a severe iritis of the left eye, which left a synechia between the iris and the anterior capsule of the lens, with loss of accommodation.

I saw her first on September 25, 1898. At that time all the above-named lesions had healed, but there were three ulcers on the right shoulder and one on the posterior wall of the pharynx, on a level with the free margin of the palate. She had noticed a swelling in this area for twelve months. The pharyngeal ulcer was about three-quarters of an inch in diameter, surrounded by soft, pulpy granulations

and covered with yellow, foul-smelling pus. At the bottom of the ulcer there was a sinus from which pus constantly exuded. A probe was passed in the sinus down to the cervical vertebra; the bone was hard and resistant and no rough or necrosed areas could be detected.

She had not been able to lie down for six months; the only rest she obtained was by reclining in a Morris chair. But little sleep was obtained on account of the pain, gnawing in character, worse at night and preceding and during stormy weather, and most marked on the left side. She described it as if cords were pulling from every direction toward a common center. When she wished to get up or sit down, she was compelled to steady her head by clasping both hands behind her neck, holding the head rigid until she was erect or the head rested against the back of the chair. Attempts to move without this support caused a feeling as if her neck would break.

*Treatment.*—The ulcer was cleansed daily with a cotton-wrapped probe, dipped in hydrogen peroxide, full strength, and the granulations touched twice a week with a 20-per-cent. solution of chromic acid. From the history it was ascertained that she had been given the iodides and mercury for about three years until the stomach had rebelled and could tolerate it no longer. I was very much puzzled to know what to give her, knowing full well that local without internal treatment would avail nothing. I reasoned thus: the effect of the iodides depend upon the iodine radical and not upon the base. I therefore decided to try temporarily a compound wine of iodine, the formula of which is as follows: Iodine and bromine, $\overline{aa}$ gr. $\frac{1}{8}$; phosphorus, gr. $\frac{1}{100}$; sherry wine, 3 i. One teaspoonful was ordered three times a day after meals. The bowels were kept regular by the use of sodium phosphate and occasional doses of calomel. Early in the treatment, at different times and without the patient's knowledge, potassium iodide was substituted, but each time she said it was the same she had taken before and that it caused pain and nausea.

In about three weeks the ulcer looked healthier and apparently was healing; but soon after it broke down and was as bad as at the beginning, yet no necrosed bone could be detected. About the middle of November—two months after the first visit—a small piece of bone was seen protruding in the sinus. With a probe it could be moved slightly, but was not entirely free. These manipulations caused much pain, referred to the left side of the neck. Not being able to locate the seat and extent of necrosis, no attempt was made to tear the fragment of bone loose for fear of injury to the spinal cord. At each subsequent visit the bone was gently moved, and it gradually became looser and protruded further in the sinus, until December 19, when it was free from all attachment, and with a pair of forceps I removed it. There was no bleeding. The bone was three-fourths of an inch by an inch, and full of holes like worm-eaten wood. The treatment was continued, and again the sinus appeared to be healing, but it did not close nor did the discharge entirely cease. In March the ulceration was worse again and another piece of bone protruded. This was extracted on April 13, 1899. It was half an inch square and full of holes similar to the first piece. On May 1 the ulcer had firmly healed and has remained healed ever since. There is a depression of one-quarter inch deep and an inch in diameter over the area involved. Thus far (four years) there have been no symptoms of other lesions.

During the height of the disease there was much pain in the left side of the neck, extending to the shoulder and down the arm. There was so great pain when attempting to swallow she could eat and drink but very little, but there was no regurgitation through the nose. The symptoms gradually became less severe, the stiffness in the neck and the darting pains subsided; but for six months, like chronic rheumatics, she complained of a dull, aching pain in the neck preceding stormy weather.

Three months after this treatment was begun she was again able to lie down and rest better, and finally slept through the entire night.

The internal treatment was continued for two years and a half, then five days each week. The intervals without treatment were gradually lengthened, and finally discontinued at the end of three years.

This case is of special interest on account not only of its rarity, but also of the result of the internal treatment used. It proves that in this wine of iodine we have a remedy that is efficacious when iodine or the iodides are indicated; besides it is palatable, and in this case was well borne for three years, even after the stomach had rebelled from the use of the iodides.

In a careful search of the literature I can find but few similar cases reported.

Allin[1], in a most excellent review of post pharyngeal abscess, collected and tabulated 58 cases; 6 were due to or complicated by cervical necrosis, 4 of which were syphilitic.

Morell Mackenzie[2] cites a case with severe hemorrhage, which was believed to come from the vertebral artery; more than a quart of blood was lost. She soon afterward expectorated the transverse process of the second cervical vertebra.

S. H. Chapman[3] reported a case in which the initial lesion appeared six years previously. The throat manifestations were: Ulceration and necrosis of the turbinals, septum, gums, and inside of the mouth and pharynx; infiltration and inflammation of the larynx; and an abscess over the third cervical vertebra, with necrosed bone. A piece of the third cervical, and four weeks later two pieces of the fourth cervical vertebra were extracted. The pharynx healed three months after the first operation; the posterior pharyngeal wall remaining concave.

**Perceptions of the Poor.**—A writer in the *Daily News* says that it is not because the nature or senses are duller than that of more refined persons that the poor inhabitants of our unwholesome alleys are only partly conscious of the unpleasantness of their surroundings, but because their circumstances and their constant subjection have deadened their faculty of perception. And it is not so many generations ago that the same was true of the higher classes in an equal degree.

**Training Volunteer Medical Units.**—Mr. William Sheen says that the ideals of a volunteer medical unit should be (1) to be able to render medical assistance in time of war; (2) to render in peace medical assistance to the combatant force to which it is attached, particularly (*a*) in camp, (*b*) on field days, (*c*) at ceremonial parades, dealing with emergencies in crowds when the military guard the streets, and (3) by teaching the men first aid and ambulance work to furnish more useful citizens.

# Book Reviews.

CHART OF THE ARTERIAL, VENUS, AND NERVOUS SYSTEMS. Cleveland, Ohio: Dr. Gustave H. Michel & Co., 1903.

IN this wall-chart we have represented the course of all the large arteries, veins, and nerve trunks, together with their branches supplying the various organs and viscera. They are distinguished by the conventional red, blue, and yellow coloration. The chart offers a convenient work of reference, and might be of invaluable assistance to one called upon to act hurriedly without the time to refer to a textbook or atlas for the information here given at a glance.

THE MEDICAL EPITOME SERIES. MICROSCOPY AND BACTERIOLOGY. By P. E. ARCHINARD, A.M., M.D., Demonstrator of Microscopy and Bacteriology, Tulane University. Philadelphia and New York: Lea Brothers & Co., 1903.

AFTER a general introduction on the microscope and the fundamental principles of bacteriology, the examination, staining, and cultivation of bacteria are taken up. Methods of sterilization and disinfection and animal inoculations are next considered, and then the pathogenic bacteria and micrococci. Several chapters follow, dealing more in detail with the important bacilli and other microorganisms. The closing chapter gives a brief account of the bacteriological examination of water, air, and soil. The book should prove useful to both students and practitioners.

LA CURE DE LA TUBERCULOSE DANS LES SANATORIUMS FRANÇAIS. Par les Docteurs A. F. Plicque et Verhaeren Paris: C. Naud, 1903

TRATAMIENTO CURATIVO DE LA TUBERCULOSIS PULMONAR (Cuatro Años de Experimentación Clínica). Por el Dr. Abdón Sánchez Herrero, Madrid, 1903.

THESE two brochures cover practically the same ground. In the former are chapters on the cure by air, rest, hyperalimentation, antisepsis, etc., and a special chapter on the organization of sanatoria for tuberculous patients, together with illustrations of some of the more noted French institutions of this class. It is an excellent presentation of the civic and ethical as well as of the general medical aspects of the tuberculosis question. Much stress is laid (and properly so) on the personal rôle of the physician. The authors declare that sanatorium treatment, if possible, is preferable to home treatment because of the great personal and, one might almost say, direct moral influence arising from having constantly at hand one who will encourage and gain the full confidence of the patient. Varying results of different institutions are largely, attributable to this personal influence of those in charge.

The work of the Spanish author is more a record of personal experience, which gives in great detail the results following the use of the various measures now in vogue. He frankly states his bad results as well as his good ones. While these publications, perhaps, contain nothing new, they are honest contributions to the great tuberculosis question.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, etc. Assisted by H. R. M. LANDIS, M.D., Assistant Physician to the Out-patient Medical Department of the Jefferson Medical College Hospital. Volume II, June, 1903. Surgery of the Abdomen, including Hernia, Gynecology. Diseases of the Blood and Ductless Glands. The Hemorrhagic Diseases. Ophthalmology. Philadelphia and New York: Lea Brothers & Co., 1903.

THE contributors to this volume are Clark, Coley, Jackson, and Stengel. Their subjects are Gynecology, Surgery of the Abdomen, Ophthalmology, and Diseases of the Blood and Ductless Glands, the Hemorrhagic Diseases, Metabolic Diseases.

Their work has been as well done as the standard of the publication demands that it should be.

RADIUM AND OTHER RADIO-ACTIVE SUBSTANCES; Polonium, Actinium and Thorium, with a Consideration of Phosphorescent and Fluorescent Substances, the Properties and Applications of Selenium and the Treatment of Disease by the Ultraviolet Light. By WILLIAM T. HAMMER, Consulting Electrical Engineer. New York: D. Van Nostrand Company, 1903.

MUCH interest in the subject of radium has been excited, first among scientists the world over, then in a popular way, and finally physicians have been forced to take, beside the natural popular and scientific interest in a new discovery, a closer professional one because of the reputed therapeutic properties of this new form of energy. The whole question is one of wonder, and fraught with scarcely conceivable possibilities. In medicine, however, where all is hoped for and so little attained one must be skeptical. Liquid air, tuberculin, *x*-ray, have all had more expected of them than could be realized. There is no good reason to believe that radium will prove an exception. It has already been shown to be of value.

Mr. Hammer's book takes up the source, physical qualities, properties, and powers of the new element. There is necessarily little on the therapeutic use, as sufficient time has not elapsed to know much about it.

For so small a volume a vast amount of information has been crowded in. There are additional chapters on Selenium and treatment of disease by the ultraviolet ray. This is very short, still it seems a little out of place in a work by an Electrical Engineer, written from the broader scientific standpoint.

SYPHILIS IN DENTISTRY. By L. BLAKE BALDWIN, M.D., Chicago, Ill. Professor of Dermatology and Venereal Diseases, Post-Graduate Medical School; and EZRA READ LARNED, M.D., Chicago, Member of the American Association for the Advancement of Science. Chicago: E. H. Colegrove, 1903.

THIS is a very important subject and one with which dentists are either strangely unfamiliar or of which thoughtlessly negligent. Much accidental syphilis occurs each year, and a small proportion of it can be traced to fault of aseptic technique on the part of the dentist. Anything tending to increase knowledge and recollection of the possibilities in this direction is welcome, and to this end we commend the present small volume.

A COMPEND OF HUMAN ANATOMY. By SAMUEL O. L. POTTER, M.A., M.D., M.R.C.P. London., formerly Professor of the Principles and Practice of Medicine in the Cooper Medical College of San Francisco; author of the "Handbook of Materia Medica, Pharmacy, and Therapeutics," Quiz-Compend of Materia Medica," "Index of Comparative Therapeutics," and "Speech and Its Defects"; late Major and Surgeon of Volunteers, United States Army. Seventh edition, Revised and Enlarged. Philadelphia: P. Blakiston's Sons & Co., 1903.

THIS is one of the series of quiz-compends issued by the publishers, and the fact that it passed through six editions in the course of twenty years affords satisfactory testimony as to its value. The author states that the present edition has been entirely rewritten, the text being brought into harmony with the most recent anatomical textbooks. About twenty additional illustrations have been inserted and several of the old cuts have been replaced by newer ones. Although intended primarily for students and for others preparing for examination, the little work will serve in a very satisfactory way as a book of ready reference for the practitioner who wishes to jog a halting memory in an emergency and has not the time or the opportunity to consult one of the larger treatises.

CONSUMPTION, A CURABLE AND PREVENTABLE DISEASE. What a Layman Should Know About It. By LAWRENCE F. FLICK, M.D., Medical Director of the Henry Phipps Institute for the Study and Prevention of Tuberculosis. 295 pages. Philadelphia: David McKay, 1903. Price, $1.00.

THIS is a sane study of a great problem. The author is an anti-alarmist, and his words may be profitably read and pondered over by physicians as well as by laymen. He presents his views in simple language, entirely free from the lurid expressions so often found in books on this topic. From a careful examination of his pages our verdict is that they form the best presentation of the tuberculosis problem, socially and ethically considered, that has yet appeared.

DISEASES OF THE EAR. A Textbook for Practitioners and Students of Medicine. By EDWARD BRADFORD DENCH, Ph.B., M.D., Professor of Diseases of the Ear in the University and Bellevue Hospital Medical College. With fifteen plates and one hundred and fifty-eight illustrations in the text. Third edition, revised and enlarged. 718 pages. New York and London: D. Appleton & Co., 1903.

IN commenting on this work, mention need be made only of those features wherein it differs from preceding editions. These consist mainly of the sections devoted to the surgical aspects of modern otology. The advances of the last few years have required the rewriting of a considerable portion of Dr. Dench's treatise. Particularly is this true with reference to the operative treatment of chronic suppurative otitis media and the various intracranial complications of middle ear suppuration. These receive full and discriminating consideration in the present edition. The author notes his failures as well as his successes with each procedure, and his pages bear the impress of frankness as well as of a detailed knowledge of the questions discussed. His standing in the field of otology is too well known to call for any perfunctory praise. The typographical appearance of the book is, in our judgment, more attractive than that of the former editions. Not the least valuable feature is the elaborate index covering some twenty pages and rendering reference to any topic extremely easy.

# Society Reports.

## AMERICAN LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL SOCIETY.

*Ninth Annual Meeting, Held in Lexington, Ky., April 30, May 1 and 2, 1903.*

J. A. STUCKY, M.D., OF LEXINGTON, KY., PRESIDENT.

*Thursday, April 30—First Day.*

**A Case of Lipoma of the Tonsil.**—Dr. CLEMENT F. THEISEN of Albany, N. Y., reported this case. The patient was an eight-year-old girl who had suffered for several years from a paroxysmal cough. A smooth, yellowish tumor about the size of a marble was found attached to the right tonsil by a pedicle, and proved, on examination by Dr. G. W. Blumer, to be a lipoma. He had found only six other similar cases on record, the majority of which had occurred in adults.

**Retropharyngeal Abscess.**—Dr. LEWIS C. CLINE of Indianapolis presented in this paper a report of three cases. The first case was a child of about five years, with a distinct one-sided swelling of the neck, a croaking cough, dyspnœa, and fever. The abscess was incised, and as soon as effective drainage had been secured the case did well. The second case occurred in a man, who complained of a troublesome spasmodic cough, and presented a large swelling on the posterior pharyngeal wall. A long incision was made in the median line from below upward, and some pus and débris evacuated. The man was markedly septic, and died about two weeks later during an attack of coughing. In this case the abscess was thought to be of tuberculous origin. The third case occurred in a child of two and a half years, the abscess developing immediately after an attack of measles. There was a croupy, paroxysmal cough, and examination revealed a large swelling on the posterior pharyngeal wall. Recovery was rapid after a free incision of this abscess.

Dr. C. G. COAKLEY of New York said that although he saw about half a dozen such cases at the clinic every winter, he had only met with one retropharyngeal abscess in private practice, and that was in a man thirty years of age. In that case there was no enlargement of the tonsil or œdema of the faucial pillars, and incision gave prompt relief. The incision should be made in the mouth far down in the median line, and should be coextensive with the swelling. Immediately after making this incision, the patient's head should be lowered, and the escape of pus aided by pressure with the finger. He had never met with any serious complication arising from the passage of the pus into the air passages. The old hatchet-shaped gum lancet was useful for opening these abscesses.

Dr. F. C. COBB of Boston was also of the opinion that there was little danger of the suffocation of the patient by the passage of pus into the air passages. It was important to make a very free incision and to see that this opening did not close prematurely.

Dr. GEORGE L. RICHARDS of Fall River, Mass., believed the condition was often overlooked, and that this explained its apparent rarity. He incised these abscesses both upward and downward, sometimes for a distance of two inches, and then swabbed out the abscess cavity with a strong solution of hydrogen dioxide.

Dr. W. H. DUDLEY of Easton, Pa., recalled a case that had come to him with a history of paralysis of one of the ocular muscles. Incision of the abscess gave prompt and permanent relief.

Dr. J. M. RAY of Louisville said he had not found these abscesses very rare in nursing infants. A case was reported in which the condition had resulted from traumatism.

Dr. CHEVALIER JACKSON of Pittsburgh said that for opening a retropharyngeal abscess through the mouth he used a bistoury or scalpel having the greater part of the blade guarded by wrapping it with adhesive plaster.

**A Case of Tuberculous Laryngeal Stenosis Treated by Tracheotomy.**—Dr. PRICE BROWN of Toronto presented this paper. The patient was a man, thirty-one years of age. Under cleansing sprays and applications of a fifty per cent. solution of lactic acid the patient's condition improved considerably, but the lungs then showed evidences of tuberculosis. Life in a tent for eleven months resulted in great improvement, but finally an attack of œdema of the larynx necessitated the performance of a high tracheotomy. Since that operation the laryngeal symptoms had improved, and at the present time there were no visible ulcers in the larynx, no bacilli could be detected in the sputum and the man had regained his normal weight.

Dr. JOHN A. THOMPSON of Cincinnati said that while admitting the danger of infection of the tissues of the neck by tracheotomy, he could not but feel that this operation was indicated in those rather rare cases of tuberculous laryngitis characterized by extensive infiltration and but little disease of the lungs.

**The Pathology of Ethmoiditis Reconsidered.**—Dr. EDWARD WOAKES of London, England, sent a paper on this subject. He took the ground that this disease certainly had a specific character. In the first stage the changes were only in the mucous membrane; in the second stage the small arteries of the submucosa were invaded and a myxœdema developed, the bone itself becoming thinner by absorption.

**The Import of the Salivary and Nasal Secretions in Hay-fever.**—Dr. D. BRADEN KYLE of Philadelphia presented this paper. He said that his studies of the past eight years had convinced him that the saliva was an index to important changes in the chemical processes of the body. After examining the saliva in normal persons and in hay-fever patients he had become convinced that the irritation leading to the attack of hay-fever often had its origin in a chemical change in the saliva. He had known a teaspoonful of common salt, swallowed at one dose, to abort an attack of hay-fever. In the attacks of so-called hay-fever which came on suddenly without apparent exposure to cold or other source of irritation, he believed that through an alteration in the chemical composition of the saliva substances were formed which, on exposure to the air, decomposed into irritants. Normally the sulphocyanides and ammonium salts were present in the saliva in about equal proportions, but in many of the cases alluded to these compounds were present in excess. When there was diminished acidity the sulphocyanides were not so abundant as the ammonium salts, and the secretion became more irritating.

Dr. NORVAL H. PIERCE of Chicago said that too little attention had been paid in the past to the chemical changes taking place in the secretions of the body. He believed the time would come when it could be demonstrated that heat and light were capable of producing the changes found in hyperæsthetic rhinorrhœa. A case was mentioned in which, after an excess of eating or drinking, the taking of a drachm of phosphate of soda would prevent an attack of pharyngitis; and another in which the taking of bicarbonate of sodium would cut short an attack of rhinitis.

Dr. F. C. COBB said that while this theory might apply to certain cases, it was difficult to believe that a rhinitis resulting, for example, from riding behind a horse, could have such an origin as was suggested by the paper.

Dr. H. HOLBROOK CURTIS of New York was disposed to divide cases of hay-fever into three classes, viz., (1) those due to a systemic condition, *e.g.* explosions of uric acid in the blood or the occurrence of chemical changes described in the paper; (2) those due to a local condition whereby the application of certain pollens or other irritants precipitated an attack of hay-fever, and (3) those dependent upon a neurotic condition.

Dr. C. F. THEISEN said that it was difficult to reconcile Dr. Kyle's theory with the results of the recent investigations of Dunbar of Hamburg. We should distinguish

between typical hay-fever and what the Germans styled *rhinitis nervosa.*

Dr. COAKLEY thought many of Dr. Kyle's statements tended to confirm the results obtained by Dunbar.

Dr. PRICE BROWN of Toronto referred to a long standing case of hay-fever that he had succeeded in benefiting by insisting upon the patient going to the country during the summer and working laboriously. The customary attack of hay-fever did not come, a fact which Dr. Brown was disposed to explain on the theory of a chemical alteration in the secretions.

Dr. S. MACCUEN SMITH of Philadelphia said that it was a tradition in his locality that hay-fever could be relieved by taking a teaspoonful of table salt in one or two pints of hot water on retiring, and it was certainly true that this simple treatment would abort many cases.

Dr. J. A. STUCKY of Lexington said that he had, in a previous paper, called attendion to the dependence of these neuroses on intestinal intoxication, as indicated by the presence in the urine of an excess of indican. He had observed this excess in eleven out of seventeen cases studied. It was worthy of note that hay-fever was extremely rare among the laboring class.

Dr. Kyle, in closing the discussion, said he had not claimed that all cases of hay-fever were dependent upon alterations in the secretions.

**A Case of Bilateral Abscess of the Septum with Well-marked Symptoms of Septicæmia.**—Dr. W. L. CULBERT of New York reported this case, occurring in a man aged thirty-one years. When first seen his temperature was 104° F. and pulse 132; the nose was completely occluded; he complained of an intense throbbing pain, and examination showed two abscesses of the septum. Both were opened by a vertical and horizontal incision, and the cavities were irrigated with hydrogen dioxide and lightly packed. The symptoms rapidly subsided, and five days later the man returned with a quadrangular sequestrum that had been discharged from the nose. The fact that the abscess was bilateral and involved both the cartilaginous and bony septum was of some interest.

**A Case of Epiglottic Abscess with Secondary Involvement of the Cervical Glands.**—Dr. CULBERT also reported this case, occurring in a man of thirty-four years, of gouty habit. The anterior chain of lymphatic cervical glands was swollen and tender. The abscess was opened with a sharp curved aneurysm needle, and the enlargement of the glands rapidly subsided.

Dr. GEORGE L. RICHARDS reported a case of septal abscess with septicæmia occurring in a physician as a result of an injury to the nose. When first seen by the speaker the abscess had already been incised, but the patient's temperature was 103° F. and he was complaining of pain in one knee. Finally it became necessary to open several small abscesses, and convalescence was tedious. Some of these cases of abscess of the septum left marked deformity of the bridge of the nose.

Dr. COAKLEY also spoke of the tendency in these cases of the cartilage to break down suddenly, and suggested that deformity could, to a certain extent at least, be prevented by keeping the parts in position by the use of the Simpson tampon.

Dr. W. L. BALLENGER of Chicago said that the amount of septicæmia present in the case reported by Dr. Culbert suggested that there had been an extension of the infection to a part more richly supplied with lymphatics than the cartilaginous portion of the septum.

**The Relations of the Upper Air Passages to Diseases of the Gastrointestinal Tract.**—Dr. L. A. COFFIN of New York was the author of this paper. He said that he had been impressed with the large number of his clinic patients whose sole complaint was of postnasal catarrh. The circumscribed area affected was against the view that the condition was the result of a general toxæmia. Children, who seldom had great structural deformity of the nose, were quite as frequently affected with this disorder as adults. His own opinion was that the chief cause was to be found in the irritation resulting from the eructation of gases from the stomach, and that better therapeutic results would follow from treatment based on the belief that chronic follicular pharyngitis and nasopharyngitis were frequently secondary to chronic indigestion.

Dr. JOSEPH A. WHITE of Richmond, Va., said that he had not been fully convinced by the author's statements. Years ago he had been taught that all disorders of the upper air passages were dependent upon digestive, and especially liver, trouble. Since then rheumatism, smoking, drinking, and other etiological factors had been brought forward. Mere refrigeration was usually nothing more than defective circulation, though this might in turn be dependent upon digestive disorder. The old treatment, still employed by many physicians, was to give calomel and a saline. He was personally disposed to think that gastrointestinal trouble arose from the condition of the upper air passages, and not that the reverse was true.

Dr. W. L. BALLENGER observed that the lymphoid tissue of children was very prone to inflammation on slight irritation; hence it did not follow that the frequency of postnasal catarrh in young subjects was due to eructation of gases from the stomach or the regurgitation of irritating fluids.

Dr. S. MACCUEN SMITH said that many cases of dry throat would show remarkable improvement if given hydrochloric acid twenty minutes after meals instead of immediately afterward. Coryza and hoarseness were often associated with so-called bilious attacks, and it was his custom to treat such cases by calomel and a saline, and then give half a grain to one grain of mercury and chalk every night for a number of weeks.

Dr. J. A. THOMPSON of Cincinnati said that certain forms of laryngitis often proved most rebellious until gastric hyperacidity was detected and appropriately treated. The regurgitation of irritating secretions during sleep was often the cause of a pharyngitis or a rhinitis.

Dr. L. C. CLINE remarked that if this line of investigation were pursued more generally there would be found less use for the saw and cautery.

Dr. PRICE BROWN thought that if one made sure the nasopharynx was free from hypertrophied tissue, little else would be required further than some attention to the general health.

Dr. L. A. MCCLELLAND of Brooklyn remarked that many cases of acute and chronic pharyngitis would improve very rapidly under large doses of calomel and jalap, followed by a saline, without local treatment.

Dr. DUNBAR ROY of Atlanta said that the chronic nasopharyngitis of chronic drinkers was associated with gastric catarrh and that both conditions would be relieved simply by a withdrawal of the stimulant. However, there were cases of nasopharyngeal bursitis existing independently of stomach disorder, and proving most obstinate to treatment.

Dr. WENDELL C. PHILLIPS of New York said that many of the affections of the nasopharynx were not necessarily dependent upon gaseous eructations or the regurgitation of irritating fluids, but were rather dependent upon an altered state of the secretions. He had found it best to treat such cases by administering half a grain of calomel and half a drachm of bicarbonate of soda every hour for five or six doses.

Dr. Coffin, in closing the discussion, said he had endeavored to eliminate toxæmia from consideration, for the throat that was benefited by calomel was not the kind he had endeavored to describe.

*Friday, May 1—Second Day.*

**Symposium on Otitis Media Suppurativa.**—This comprised the following papers:

**Etiology and Pathology of Acute Otitis Media.**—Dr. NORVAL H. PIERCE of Chicago presented this paper. He said that the microorganisms most commonly met with

were the streptococcus, the staphylococcus and the diplococcus pneumoniæ, and that while mixed infection was the rule, the staphylococcus pyogenes was sometimes present in pure culture. The fact that the mucous membrane of the ear served both as mucous membrane and as periosteum explained the tendency of inflammation in this region to lead to necrosis.

**Treatment of Otitis Media.**—Dr. S. MacCuen Smith of Philadelphia considered this subject. He pointed out that prompt and proper care of an acute otitis media would usually prevent suppuration, or if it had already occurred would lead to recovery without loss of function. The cases arising in connection with pneumonia or grip were usually purulent and required heroic treatment. Both the quantity and quality of the discharge were important in considering prognosis and treatment. An odorless discharge might contain pathogenic micrococci capable of doing great mischief, while a fetid discharge sometimes contained only non-pathogenic organisms. In the case of children suffering from grip, pneumonia or the exanthemata, the physician should be ever watchful for ear complications. When pus was present in the middle ear, it should be evacuated, not through a puncture, but by means of a free incision made sufficiently low to secure good drainage. It was generally well to wait until there was some bulging of the membrana tympani, but this rule should not be observed in cases of otitis complicating pneumonia, grip, or the exanthemata. After securing drainage, the parts should be kept dry and lightly dusted with aristol, and the patient should be kept in bed on a fluid diet and with the bowels open.

**Etiology, Symptomatology, and Pathology of Otitis Media Suppurativa Chronica.**—Dr. Charles W. Richardson of Washington, D. C., presented this paper. The following were enumerated as the most frequent causes of this affection: (1) Improper treatment of the first stage; (2) certain constitutional disorders, *e.g.* tuberculosis, syphilis, and anæmia; (3) an acute suppurative otitis occurring in connection with certain acute infectious diseases; (4) differences in the virulence of the bacilli; (5) local changes, such as the development of granulation tissue, caries of the ossicles or tympanic wall; (6) retention of the discharge, and (7) local changes in the nasal and nasopharyngeal cavities. Caries, with necrosis of the ossicles, was the most common bone lesion. The stapes usually escaped. Otorrhœa was the most common symptom, pain rarely being present except when there was retention of the discharge. One perforation of the drum was the rule, and the border of the perforation was usually of a deeper color than the rest of the membrane.

**The Inefficiency of the Wilde Incision.**—Dr. J. M. Ray of Louisville read this paper. He said that the profession generally was not aware of the change of opinion that had taken place among otologists regarding this operation. Any operation which did not open up a communication with the middle ear and give free vent to the pus was unsurgical. The fact could not be too strongly emphasized that the antrum was involved in nearly every case of acute suppuration of the middle ear, and that the opening up of the one cell communicating with the tympanic cavity was absolutely necessary.

**Treatment of the Complications of Otitis Media Suppurativa.**—Dr. James F. McKernon of New York was the author of this paper. The cardinal principle for the treatment of lesions of the drum membrane was cleanliness and the application of some astringent, such as nitrate of silver. Later on, catheterization and vaporization of the Eustachian tube were useful in adults, and the Politzer bag in children. In such cases it was useful to close the opening in the membrane temporarily with collodion or by a bit of paper held in place by vaselin. If the mastoid were diseased the radical Schwartze-Stacke operation should be done. After the removal of the malleus and incus the tympanic walls and vaults should be curetted, the cavity wiped dry and a wick of iodoform gauze inserted for twenty-four hours. When there was tenderness over the mastoid an ice coil should be used for twenty-four hours. Only in case of improvement was it justifiable to continue the coil for twelve hours longer. Neither cold nor heat should be employed if the mastoiditis had lasted for several days or if œdema were present. To make the primary dressing comfortable to the patient in a mastoid operation, a piece of sterile rubber tissue, buttonholed in places, should be first introduced and the gauze packing placed on this.

**Intracranial Complications.**—Pachymeningitis was the most common of the intracranial complications. Sinus thrombosis most commonly occurred in the lateral or sigmoid sinus. There must be complete exposure of the sinus, and the part above the bend should be opened, for experience had shown that the aspirating needle was not to be depended upon. If a large clot were present it should be removed with the curette and the bleeding be allowed to continue long enough to remove septic matter. If, on opening the sinus, there was present a disintegrating clot, the vein should be resected, and the wound sutured to within a short distance of the bulb, a wick drain being inserted for forty-eight hours. The inferior petrosal sinus was frequently thrombosed in connection with the bulbous portion of the sigmoid sinus. About 37 per cent. of all cases of brain abscess were of otitic origin, and the most common site for subdural accumulation of pus was the inferior and posterior portion of the temperosphenoidal lobe. An aspirating needle of largec aliber might be used for exploring the brain, and when pus was found a sufficiently large opening should be made to secure thorough evacuation of the pus. The cavity should then be cleansed by gentle irrigation with warm saline solution or by mopping with gauze. The operation should be rapidly and gently done, and gauze wicks used for drainage. In exploring the temperosphenoidal region the bone should be removed at a point one inch and a half above, and the same distance behind, the bony meatus. The skull should be entered at a point as near as possible to the floor of the lobe to be explored in order to secure good drainage. When meningitis was present and could not be localized little was to be hoped for from surgical procedures. Metastatic abscesses in different parts of the body should be treated on general surgical principles. Facial paralysis not uncommonly followed middle ear suppuration. When it occurred several days after an operation for the removal of carious bone it was to be explained by concussion or by destruction of the facial branch of the chorda tympani. If it occurred immediately after an operation on the middle ear it was probable that the nerve had been severed. The local treatment of labyrinthian affections consisted in placing the patient in bed and administering hypodermically full doses of pilocarpin for six weeks. Potassium bromide in full doses was useful for the relief of annoying subjective symptoms. When cholesteomata were present, a Stacke operation should be done for their removal.

**The Technique of the Radical Operation for Otitis Media Suppurativa Chronica.**—Dr. Edward B. Dench of New York read this paper. He insisted that the head should be shaved for three inches around the ear and that the field of operation should be most carefully sterilized. The initial incision began one-quarter of an inch behind the insertion of the lobule and ran upward and backward behind the line of auricular attachment to a point just above the apex of the auricle, and then forward and downward. The anterior flap should be pushed forward so as to expose the posterior and inferior margins of the bony meatus. Ordinarily a small portion of the fibrous meatus could be preserved. In entering the mastoid antrum it was better to remove the cortex from below, and use the gouge until the inner wall could be seen. The fibrous meatus should then be divided posteriorly close to the tympanic ring. The partition between the mastoid

antrum and the external auditory meatus was broken down by chiseling upward. As soon as the prominence in the horizontal semicircular canal came into view the parts exposed should be converted into one large cavity. All diseased bone should be removed, but only such pneumatic spaces should be obliterated as were diseased. A small curette should be passed into the tympanic orifice of the Eustachian tube and any softened bone removed. The posterior wall of the fibrocartilaginous meatus should be split into two triangular flaps. Healing might be accelerated by the use of Thiersch skin grafts, the grafts being applied rapidly so as to avoid the filling up of the wound with blood under the grafts. The latter were held in place by packing in pledgets of cotton dusted with aristol. The first change of dressing should be made on the eighth day as a rule, and the pledgets should be gradually removed at subsequent dressings. Out of twenty-eight such operations, sixteen of primary and twelve of secondary grafting, twenty-six had been cured, and two cases were still under treatment.

**Some Unusual Mastoid Cases.**—Dr. H. Bert Ellis of Los Angeles presented a paper with this title. The first case reported was of interest because of the marked mental disturbance and the small amount of disease present. The second case had a right-sided facial paralysis. The mastoid antrum and cells were opened, and in sixteen days the patient was free from paralysis. Another case of paralysis, occurring in a women of thirty, was also treated successfully. Several other interesting cases were reported.

**Some Unsuccessful Cases of Aural Surgery.**—Dr. George L. Richards of Fall River presented a report of six cases, seen between 1897 and 1903. In the first case only a partial operation was done because of profuse hemorrhage, and the patient would not consent to a subsequent operation. The second case was one of cerebral abscess, which was temporarily improved by the operation, but pneumonia supervened and death occurred on the third day with a temperature of 107.8° F. It was thought that death was probably due to pneumonia rather than to the mastoid operation. In the third case there was a history of chronic otorrhœa. There was an abscess cavity found in the temperosphenoidal lobe, which was drained. The child continued to have an irregular fever and remained in a semi-stuporous condition. Death occurred with a temperature of 107° F. No autopsy was allowed, but examination of the wound showed that there was also an abscess of the cerebellum. In the fourth case several operations and explorations were done. A small epidural abscess was found, but no pus could be detected in the temperosphenoidal region. The internal jugular vein was found to be patulous and the lateral sinus contained fluid blood. On exploring the wound after death a collection of seropurulent fluid was discovered a little deeper than the exploration had extended, and he felt that if the knife had been carried forward and inward rather than directly inward the patient might have been saved. In the fifth case, although a mastoid operation was done and on exploring the brain an abscess cavity was discovered and drained, great difficulty was encountered in securing good drainage because of the tube becoming blocked with coagula. After death examination of the wound showed a large cavity communicating with the cerebrum. The sixth case was one of intense general infection. Several mastoid operations and explorations were done, but the man did badly, and eventually died. Dr. Richards said he reported this case because he felt if cold had not been applied and a mastoid operation had been done at the very first sign of trouble further infection might have been prevented.

Dr. Wendell C. Phillips of New York said he did not now use the ice coil once where a year or two ago he employed it in ten cases. His present efforts at abortive treatment consisted in keeping the patient in bed, restricting the diet, cleansing the ear and giving purgatives. The early operation was not only safer as regards the patient's life, but his hearing was likely to be better..

Dr. S. MacCuen Smith said that this instructive paper emphasized very well the need for early and thorough interference. The ear should be frequently examined in children suffering from grip or the acute exanthemata, even in the absence of ear symptoms, and early and free incision of the drum even before there was bulging would often prove to be the most truly conservative treatment.

Dr. Ewing W. Day of Pittsburgh said that the complicated cases referred to were chiefly met with in ignorant hospital patients, and the mischief had usually been done before the case came under observation. Usually the only symptom was pain, often in the frontal region.

**Two Cases of Thrombosis of the Jugular Bulb; Ligation of the Internal Jugular Vein.**—Dr. Norval H. Pierce of Chicago reported these cases. The first case was one of isolated primary thrombosis of the jugular bulb, terminating fatally. In the second case it was thought that the thrombosis had extended up the inferior petrosal sinus, causing secondary thrombosis of the jugular bulb.

Dr. E. B. Dench said that unless it could be demonstrated that there was a very free flow of blood through the sinus the latter should be opened at the primary operation. Puncture of the sinus was not of much value as an aid to diagnosis, and he had not seen a single case in which incision of the sinus under aseptic precautions for exploratory purposes had led to an unfavorable result. He preferred to use iodoform gauze rather than plain sterile gauze in cases in which the normal sinus was surrounded by suppuration.

Dr. Pierce said that even after having exposed the sinus for a considerable distance it was difficult to say whether the sinus might not be entirely occluded by a thrombus; hence he felt that it was proper to wait twelve or twenty-four hours rather than perhaps needlessly sacrifice the sinus. If fever and chills persisted he would open the sinus.

**The Technique of Maxillary Antrum Operations.**—Dr. H. Holbrook Curtis of New York read this paper. He said that irrigations through the natural orifice should be given a trial, and if this could not be used, and the tooth was suspected to be the cause, the tooth should be sacrificed and this opening utilized for drainage. He found it easy to make obturators of varying shapes out of sheet guttapercha dipped in boiling water and wrapped around a pencil. The alveolar puncture was made for inspection, not for drainage. When a radical operation had been decided upon, the periosteum should be divided and turned back, and the antrum entered with a chisel. With bone forceps the fenestration was completed, and then the cavity was cleansed by the successive use of strong carbolic acid and alcohol, followed by peroxide of hydrogen and saline solution. After three or four weeks the worsted packing could be stopped and a peg inserted. A still better operation was to make a large opening in the nasal fossa in addition to the fenestration already described. The operation through the inferior meatus had the advantage of requiring no anæsthesia. The perforation should be made about one-quarter of an inch above the nasal floor.

**Report of an Unusual Case of Frontal Sinusitis.**—Dr. Cornelius G. Coakley of New York reported this case, one of absence of septum in the frontal sinus. The other interesting features were the very large size of the sinus and the fact that it healed without any osteoplastic operation.

Dr. Chevalier Jackson remarked that the powerful transillumination that he had presented was capable of showing the septum in the frontal sinus if this sinus were normal. In cases of disease of the maxillary antrum he kept the opening in the canine fossa patent by the use of a small cannula of malleable metal. After it had been inserted it was retained by expanding this metal by the

application of an alligator forceps. This cannula could be removed with slight force and without injury to the tissues.

Dr. THOMAS HUBBARD of Toledo objected to the use of unvulcanized guttapercha on the ground that he had found it prone to retain septic matter.

Dr. C. G. COAKLEY said he had not seen a case of antral suppuration, in which the diagnosis had been made by puncture and washing, that had not recovered after a very few washings, and his present treatment was to wash out the antrum on alternate days with normal saline solution blowing out afterward the residual fluid The middle meatus was usually too much covered by the middle turbinate to allow of utilizing this approach. When antral disease was suspected he did not hesitate to puncture, for it was attended by almost no risk if done aseptically.

Dr. N. H. PIERCE believed it was good practice to attempt to enter through the natural opening before resorting to puncture.

Dr. FRED C. COBB said that the washing certainly relieved the pain, but he doubted if it materially shortened the duration of the disease.

Dr. CURTIS remarked that the test by heat and cold often enabled one to detect disease of a tooth.

Dr. Coakley, in closing, said that in his case there was absolutely no trace of a septum having existed. Dr. C. W. Richardson had just told him of a case in which the septum was present at the first operation, but had entirely gone by the time a second operation was done.

*Saturday, May 2—Third Day.*

**The Eustachian Bougie; Its Use and Abuse.**—Dr. M. A. GOLDSTEIN of St. Louis was the author of this paper. He said that the bougie should be used as regularly in every case of otitis media chronica as ocular inspection of the membrana tympani and inflation. He had not found it more objectionable to the average patient than the use of the catheter and inflation. If the bougie were not in proper position the act of swallowing would cause it to shift, and if on withdrawal a decided kink were noted at its distal end, it was an indication that the bougie had passed between the tip of the catheter and pharyngeal wall and had not entered the tubal canal. As the bougie passed the isthmus tubi it usually produced an unpleasant sensation in the ear. The introduction of the bougie should be repeated every second or third day, as a rule. The most frequent contraindications to its use were a feeling of fulness and dulness in the ear and an increase in the subjective symptoms. He had used the electrolytic bougie with from three to five milliamperes of current in fifty cases, but the results had been no better than with the ordinary whalebone bougie, although the electrolytic bougie could be made to pass more easily. He believed the action of the current was more in the production of a mild surface cauterization than a true electrolysis.

**The Possibilities and Limitations of the Electrolytic Bougie in the Treatment of Chronic Hypertrophic Catarrhal Deafness.**—Dr. ARTHUR B. DUEL of New York sent a paper on this subject. He had received twenty-five replies to a circular letter asking for the experience of the members with this method of treatment. Of this number two stated that the method had been found of no value; seventeen were of the opinion that the tubes could be more quickly opened; nine reported the breaking of the bougie in the tube. Experience had certainly shown that the tube could be more quickly opened, and more permanently than by any other method. The wires should be inspected each time before use. The nose and nasopharynx should be washed out with Dobell's solution and the parts cocainized before employing the electrolytic bougie. The bougie should always be passed on into the tympanum. At intervals of one minute an additional milliampere might be turned on for five minutes, but if the obstruction had not been overcome further treatment should be postponed for one week. Having succeeded in passing the bougie gentle inflation should be practised after two days. This treatment should never be undertaken hurriedly.

Dr. CHEVALIER JACKSON was of the opinion that the best method of treating the tube was by leaving it alone and treating the nose and nasopharynx. He had found no greater relief from the electrolytic bougie than from other irritants, and no permanent benefit.

Dr. GEORGE L. RICHARDS said that the method called for careful selection and plenty of time. In one case the bougie had broken off in the tube, and while it had never caused the patient any discomfort, he had always been at a loss to account for it.

Dr. WENDELL C. PHILLIPS said he had used the electrolytic bougie quite extensively, and believed it was capable of yielding very good results, though, in his opinion, the electric current was only of service in facilitating the passage of the instrument.

Dr. SARGENT F. SNOW of Syracuse objected to the electrolytic treatment of deafness on the ground that it was directed solely against the obstruction of the Eustachian tube, and ignored other important factors.

Dr. W. L. BALLENGER argued that this treatment could not be of much value because the same treatment applied to urethral strictures had been quite generally abandoned. The method was apt to prove dangerous in the hands of the average practitioner.

Dr. DUNBAR ROY was of the opinion that the whalebone bougie was capable of giving just as good results as the electrolytic bougie. He never practised inflation after the passage of either bougie because he had met with one or two very severe cases of emphysema of the neck as a result of this treatment.

Dr. E. B. DENCH said that after a large experience with the electrolytic bougie he felt that it presented no very great advantages over the ordinary bougie, though it certainly could be passed more easily. He could recall only one case in which the tube had remained more patent after the lectrolytic than after the ordinary bougie.

Dr. GOLDSTEIN said that tinnitus was often relieved better by the electrolytic than by the ordinary bougie, probably as a result of the galvanic stimulation.

**A Few Remarks About Some Every-day Ear Cases.**—Dr. J. E. SHEPPARD of Brooklyn sent a paper with this title. He found that the decade containing the largest, number of cases was between thirty and forty years of age.

**The Value of Exploratory Puncture of the Membrana Tympani.**—Dr. DUNBAR ROY was the author of this paper. Two cases were reported to emphasize the importance of a more general use of exploratory puncture of the membrana tympani, even in some cases presenting few, if any, of the usual indications for this procedure.

Dr. C. F. THEISEN believed the unnecessary puncture of the drum was not to be recommended because of the danger of introducing infection from without.

Dr. S. F. SNOW heartily commended the position taken by the reader of the paper, believing that a more general adoption of this method would markedly reduce the number of mastoid cases. He had never known puncture of the membrane, if properly done, to do any harm.

**Cases of Pyogenic Brain Diseases Associated with or Caused by Acute or Chronic Nasal Suppuration.**—Dr. THOMAS HUBBARD of Toledo presented this paper. He reported several cases to bring out the fact that ozæna was a very important factor, particularly when operations were called for, and that the prognosis was necessarily bad.

Dr. PRICE BROWN said that these cases should serve to impress upon the minds of all the fact that serious results were likely to follow the neglect to keep the parts clean in cases of atrophic rhinitis or ozæna.

**Further Observations of Tic Douloureux and Cranial Neuralgia from Intranasal and Sinus Pressures.**—Dr. SARGENT F. SNOW of Syracuse read this paper, based on

an experience with twenty cases in which excision of the nerve had been demanded. Each one showed marked intracranial pressure or a collection in some of the accessory sinuses. He thought fully 80 per cent. of these cases were dependent upon intracranial pressure.

Dr. PRICE BROWN said that when the pressure was circumscribed, as from the pressure of the middle turbinate on the septum, the pain was apt to be very intense,

**Life Insurance and Diseases of the Ear.**—Dr. WENDELL C. PHILLIPS of New York was the author of this paper. From a circular letter addressed to upward of thirty life insurance companies he had learned that these companies were anxious to obtain statistics on this subject. Some of the companies accepted these risks unless the discharge from the ear contained bloody or gritty matter, indicating bone involvement. Statistics seemed to indicate that dangerous consequences from suppurative ear disease were most frequent between twenty and thirty. He would personally consider a person having a continuous discharge with a foul odor as a bad insurance risk. A large perforation should not be considered as a guarantee against extension of the necrotic process.

Dr. E. B. DENCH said that he had formerly believed that when there was a large perforation of the drum, insuring free drainage, the person was quite free from dangerous complications, but at present he would rather say that while such a person was comparatively safe, he was by no means entirely free from danger. It was probable that the radical operation removed absolutely all menace to life, even though the discharge had not been completely controlled.

Dr. DUNBAR ROY said that he would be willing to make a fairly favorable prognosis with regard to the insurance risk if there was no distinct odor.

Dr. W. L. BALLENGER mentioned a case in which he had done the radical mastoid operation on a boy of eight years, and about six years later the boy had died of meningitis, supposedly of otitic origin. An odor was sometimes present in cases totally devoid of any dangerous element.

**Teratoma of the Ear.**—Dr. WILLIAM C. BRAISLIN of Brooklyn sent a report of this case. The tumor was attached to the periosteum of the bony canal, and was enclosed in a capsule. It appeared, on section, to be studded with particles of cartilage.

---

**Disturbance of the Vasomotor Mechanism as a Factor in Diagnosis and Therapeutics.**—John P. Arnold holds that in many cases of chronic disorders, as constipation, headache, dyspepsia, insomnia, etc., while errors in diet, lack of exercise, overwork, etc., must be taken into consideration it will be found that the predisposing factor is a disturbance of the nervous mechanism controlling the parts affected. As practically all the vasomotor nerves traverse the spinal cord, and, aside from the governing center, have their cells located in the cord (with the exception of those dilator fibers present in the cranial nerves), and as every structural or functional disturbance in the organism is either preceded or accompanied by vasomotor disturbances, and as a compensatory relationship exists between the blood vessels of the spinal cord and the structures supplied by the posterior primary divisions of the spinal nerves, it will be seen that disturbances in different parts of the spinal cord will manifest themselves by disturbances of the circulation in the region supplied by the posterior primary divisions of the spinal nerves. No careful examination can fail to reveal that in chronic bronchitis, asthma, tuberculosis, and other affections of the respiratory tract, there are, in the region between the third and seventh dorsal, segments of the spinal cord, distinct manifestations of the circulatory disturbance within the cord. The author urges more frequent examination of the back in such patients.—*International Medical Magazine.*

# Therapeutic Hints.

**Enuresis Nocturna.**—

℞ Fl. ext. ergot.....
Sodium bromide.....
Tinct. of belladonna.....āā 10.0
Cinnamon water.....q. s. ad. 100.0
M. S. 4.0 three times daily for children of five years and over.

**Hæmophilia.**—Ochsner recommends large quantities of the white of eggs three or four times daily to lessen the tendency of bleeding. —*Medical News.*

**Colds in Old Persons.**—

℞ Spir. ammon. aromat..... ℥j.
Spir. chloroformi..... ℥ij.
Aq. menth. pip.....q. s. ad. ℥iij.
M. S. One teaspoonful every four hours.
—*International Clinics.*

**Hydrotherapy in Flatulence.**—Great relief may be obtained in flatulence and eructations, by the use of cold compresses applied to the abdomen in the shape of towels wrung out in cold water and left on over night.
—WORMLEY.

**Acid the Cause of Pain.**—Toothache in a carious tooth is frequently the result of an acid condition existing therein. This can usually be remedied by the application of a mild alkali to the cavity of the tooth. A small pledget of cotton saturated in a solution of sodium bicarbonate, or other alkaline salt, will answer the purpose.
—LAUDER BRUNTON.

**Headache from Ovarian Disease.**—

℞ Ammonii bromidi..... ℥vj.
Ext. hydrastis fl..... ℥ss.
Tinct. gentianæ comp..... ℥jss.
Aquæ..... ℥iv.
M. S. Dessertspoonful three times daily.
—SINKLER.

**Asthma.**—The following has been found to give great satisfaction:

℞ Tinct. phytolaccæ..... ℥ ss.
Potassii iodidi..... ℥ ij.
Syrupi simplicis.....q. s. ad. ℥ ij.
M. S. Teaspoonful four times daily.
—W. O. BUNNELL.

**Bromoform Emulsion.**—The following emulsion possesses the advantages that it contains a minimum of alcohol, permits of accurate dosage, and other medicaments may be added very easily.

℞ Bromoform..... ℥ ss.
Tinct. of tolu..... ℥ j.
Mucilage of acacia..... ℥ ij.
Syrup..... ℥ iv.
Spearmint water.....q. s. ad. ℥ ij.
M. Place the syrup in the mucilage and add the other constituents slowly with agitation. —SCOVILLE.

**Dyspnœa of Asthma.**—

℞ Chloral..... ℥ v.
Sodium nitrate..... gr. xlv.
Tinct. of stramonium..... ℥ iiss.
Simple elixir.....q. s. ad. ℥ iv.
M. S. Teaspoonful in water, every four hours.
—DAVIS.

**Prurigo of Hebra.**—

℞ Camphor..... gr. x.
Sulphur..... gr. viij.
Oil of chaulmoogra..... gr. iij.
Vaselin..... gr. Lxij.

Alcohol.....q. s. ad. ℥j.
M. S. Paint the joints with a brush and bandage them.

**The Treatment of Malignant Pustule with Serum.**—Reports of twenty-three cases of anthrax treated with Sclavo's serum come from Lazzaretti, at the clinic of the University of Sienna. One fatality was in a man aged sixty years, who was also an alcoholic, and who had malarial and syphilitic infection. The necropsy showed interstitial nephritis with early cirrhosis, and hemorrhage in the cerebrum, so that death could not be said to be due to the infection. All of the other cases were successful, though some of them were very severe. The course of the disease was cut short and the disfigurement was almost nil. Sublimate dressings were used locally.

**Chancroid.**—When the sore is not surrounded by an inflammatory zone, daily applications of Monsell's solution will be greatly beneficial. Either carbolic acid, 95 per cent., or 50 per cent. solution of zinc chloride, will give similar results, but with any of these remedies it will be necessary to cocainize before the application. All opposing surfaces should be kept apart by gauze and all surfaces should be powdered with some antiseptic powder. A solution of copper sulphate of 25 per cent. strength may be applied for periods of from fifteen to twenty minutes at a time when there is much inflammation present. And these applications may be made upon wads of cotton. The actual cautery is strongly indicated when there is any tendency to phagedæna. Moist antiseptic dressings and iodoform are indicated, and continuous drainage may be necessary in these cases. All crusts are to be removed and the sore is to be kept free from secretions.—LOUIS E. SCHMIDT.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that necessities are such that it cannot be considered under obligation to notice or review any publication received by which in the judgment of its editor will not be of interest to its readers.*

A DICTIONARY OF MEDICAL SCIENCE. By ROBLEY DUNGLISON, M.D. Twenty-third edition. Edited by THOMAS L. STEDMAN, M.D. 8vo, 1,212 pages. Illustrated. Lea Brothers & Co., Philadelphia, Pa.

THE AMERICAN POCKET MEDICAL DICTIONARY. By W. A. N. DORLAND, M.D. Fourth edition. 16mo, 566 pages. W. B. Saunders & Co., Philadelphia, Pa., Price, $2.00 net

AN AMERICAN TEXTBOOK OF SURGERY FOR PRACTITIONERS AND STUDENTS. By various authors. Edited by WM. W. KEEN, M.D., and J. WM. WHITE, M.D. 4to, 1,163 pages. Illustrated. W. B. Saunders, Philadelphia, Pa. Price, cloth, $7.00; sheep or half morocco, $8.00 net.

A TEXTBOOK OF THE PRACTICE OF MEDICINE. By FRANCIS M. ANDERS, M.D. Sixth edition. 8vo, 1,300 pages. Illustrated. W. B. Saunders & Co., Philadelphia, Pa. Price. cloth, $5.50 net; sheep or half morocco, $6.50 net.

NERVOUS AND MENTAL DISEASES. By A. CHURCH, M.D., and FRED'K PETERSON, M.D. Fourth edition. 8vo, 1,000 pages. Illustrated. W. B. Saunders. Price, cloth, $5.00 net; sheep and half morocco, $6.00 net.

A TEXTBOOK OF OPERATIVE SURGERY. By WARREN STONE BICKHAM, M.D. 8vo, 984 pages. Illustrated. W. B. Saunders. Price, cloth, $6.00 net; sheep or half morocco, $7.00 net.

A TEXTBOOK OF OBSTETRICS. By BARTON COOK HIRST, M.D. Fourth edition. 8vo, 899 pages. Illustrated. W. B. Saunders. Price, cloth, $5.00; sheep or half morocco, $6.00 net.

A TEXTBOOK UPON THE PATHOGENIC BACTERIA. By JOSEPH MCFARLAND, M.D. Fourth edition. 8vo, 629 pages. Illustrated. W. B. Saunders & Co. Price, cloth, $3.50 net.

A TEXTBOOK OF OBSTETRICS. By J. CLARENCE WEBSTER, M.D. 8vo, 767 pages. Illustrated. W. B. Saunders & Co. Price, cloth, $5.00 net; sheep or half morocco, $6.00 net.

A TEXTBOOK OF CLINICAL ANATOMY. By DANIEL N. LEINDRATH, M.D. 8vo, 515 pages. Illustrated. W. B. Saunders & Co. Price, cloth, $5.00 net; sheep or half morocco. $6.00 net.

CLINICAL EXAMINATION OF THE URINE AND URINARY DIAGNOSIS. By J. BERGER OGDEN, M.D. Second edition. 8vo, 418 pages. Illustrated. W. B. Saunders & Co. Price, cloth, $3.00 net.

A TEXTBOOK OF THE DISEASES OF WOMEN. By BARTON COOKE HIRST, M.D. 8vo, 675 pages. Illustrated. W. B. Saunders & Co. Price, cloth, $5.00 net; sheep, or half morocco, $6.00 net.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. By W. A. NEWMAN DORLAND, M.D. Third edition. 8vo, 800 pages. W. B. Saunders & Co. Price. $4.50 net.

A TEXTBOOK OF PATHOLOGY. By ALFRED STENGEL, M.D. Fourth edition. 8vo, 933 pages. Illustrated. W. B. Saunders & Co. Price, cloth, $5.00 net; sheep or half morocco, $6.00 net.

THE PRINCIPLES AND PRACTICE OF SURGERY. By GEORGE TULLY VAUGHAN, M.D. 8vo, 569 pages. Illustrated. J. B. Lippincott Company, Philadelphia, Pa.

YEAR BOOK OF THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK, 12mo, 200 pages.

**The Pathology of Smallpox.**—Wm. Royal Stokes bases the conclusions of his paper upon an autopsical study of five cases of smallpox. The early skin lesions indicate that the primary infection in smallpox takes place in the lungs, probably by inhalation. The poison, when it enters the circulation, shows a selective influence on the epithelium of the skin and respiratory tract, and many cases are probably not further affected. The serious and fatal lesions of smallpox are caused by the secondary infection from the skin and respiratory tract, and the infectious agent is usually the streptococcus pyogenes. This organism is so distributed throughout the lesions as to explain most of the visceral changes, such as thrombosis, local necrosis, and the various pulmonary changes. This streptococcic septicæmia is the most striking feature of fatal smallpox, and if it were possible to overcome this condition by a special serum, the mortality from the disease would be greatly reduced.—*Bulletin of the Johns Hopkins Hospital.*

**The Creosote Treatment of Lobar Pneumonia.**—M. N. Due, during the winter of 1901–1902, treated eighteen cases with creosote and carbonate of creosote with no death, and during the winter of 1902–1903 he had nine cases with one death. Following Dr. Van Zandt's formula, he usually gives one drop of beechwood creosote and 7½ gr. of salicylate of ammonium with syrup of acacia and water every three hours to an ordinary adult. There is usually copious sweating after the first twenty-four hours, but this can be avoided by reducing the dose of the salicylate to 5 or 3 gr. Creosote causes amelioration of all the symptoms; breathing is almost normal, there is no pain after the first twelve hours, no need of morphine or anodynes, no delirium. Van Zandt has tabulated 1,130 cases treated with creosote by different physicians in different sections of the United States. This table shows fifty-five deaths, or a little less than 5 per cent. The mortality under the expectant or symptomatic treatment is 20 to 25 per cent.—*The Alabama Medical Journal.*

# Medical Items.

**Contagious Diseases — Weekly Statement.** — Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending September 26, 1803:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 69 | 5 |
| Diphtheria and croup | 249 | 30 |
| Scarlet fever | 68 | 4 |
| Smallpox | ... | ... |
| Varicella | 23 | ... |
| Tuberculosis | 264 | 139 |
| Typhoid fever | 118 | 12 |
| Cerebrospinal meningitis | ... | 5 |

**An Infectious Ambulance Service in Berlin.**—An ambulance service for the transport to hospital of children suffering from infectious diseases has been established in Berlin. There are to be stations in various parts of the city. After the conveyance of a patient the ambulance van will be disinfected.—*British Medical Journal*

**The M.A. Degree at Oxford and Cambridge.**—The most stupendous of all academic frauds is none other than the M.A. degree of either Oxford or Cambridge. Year by year hundreds of graduates exchange the B.A. for M.A. without having added one iota to their scholarship, and merely by virtue of a payment of money. From this dubious source the universities in question derive a handsome, but wholly indefensible, revenue, to the disadvantage of London M.A.'s, who have to face a stiff examination. It is surely an anachronism that a university should grant a supposed honor, not as a reward for intellectual—or even athletic—achievement, but solely in order to "raise the wind"—a policy which inflicts grave disadvantages upon the poor man who may have taken high honors, and yet be unable to buy a master's gown. When Oxford and Cambridge abolish their bogus degrees, it will be time enough to censure America.—*London Daily News.*

**Post-graduate Study in London.**—The Association of London Hospitals and Medical Schools is enlarging its scope. The London Hospital has recently joined the association which now embraces all the institutions recognized by the University of London for medical education, viz., *General Hospitals:* Charing Cross, Guy's, King's College, London, Middlesex, St. Bartholomew's, St. George's, St. Mary's, St. Thomas's, University College, and Westminister. *Special Hospitals:* The Brompton Hospital for Diseases of the Chest, the Hospital for Sick Children, Great Ormond-street, the London School of Tropical Medicine, the National Hospital for the Paralyzed and Epileptic, and the Royal London Ophthalmic Hospital. The wealth of clinical material in London is great, but its value for post-graduate instruction is diminished by the extent of the area over which it is spread and by the lack of connection between the various hospitals in which it is contained. The difficulty of lack of coördination, is to a large extent met by the present scheme. The fee is seven guineas for a three months' course and ten guineas for six months.

**Observations on Akatama, a West Central African Disease.**—Frederick Creighton Wellman defines this disease as an endemic peripheral neuritis of obscure origin, characterized by numbness and intense prickling and burning sensations in the presence of cold or damp, which are temporarily relieved by the application of dry heat. The trouble affects young and old, male and female. It is found oftener in men than in women, in the young and middle-aged than in the old, and not at all in children and Europeans. The severity of the symptoms and their character indicate that akatama is a true neuritis and not a neurosis. The erythema is particularly noticeable on light-colored natives. There is often some swelling, which generally subsides as the patient gets warm over a fire or in the sun. Excessive sweating of the affected part is sometimes noticed. These symptoms generally appear on the legs and forearms, sometimes on the thighs and arms, and occasionally on any part or all over the body. In severe cases the walk is peculiar, there being a tendency to curl the toes. The diagnosis is easy. The prognosis is good as to life and general health, uncertain as to relief. As to treatment, the writer has not had encouraging experiences. Some cases he has put on cod-liver oil and arsenic, others on the bromides; again, others on phosphorus. Generally, rubifacients were prescribed. He has never succeeded in a cure. The cases without treatment seem to do as well as those treated. In malarial cases quinine improved the general health, but seemed to have no effect on the akatama. The trouble is said sometimes to cease spontaneously after years of suffering.—*The Journal of Tropical Medicine.*

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U S. Marine Hospital Service, during the week ended September 26, 1903:

### FIBROCYSTIC TUMORS OF THE UTERUS; THEIR ETIOLOGY.

By MARY A. DIXON JONES, M.D., F.R.M.S.,
NEW YORK.

THESE are most remarkable formations; and especially interesting on account of their pathological structure. But they more demand our attention that they are invariably accompanied by grave and complicated conditions, giving evidence of long existing and increasing disease. Many of our special works in this department of medicine do not speak of, or refer to fibrocystic tumors of the uterus; even excellent works on pathology, which aim at giving an account of tumors in general, few mention, or make any reference to these peculiar growths; yet, *any uterus that is diseased, or whose tissues are inflamed, which is always the case in infection, there may be developed a fibrocystic tumor.*

The etiology of these formations, and the accompanying pathological changes, prove that there must be serious disease existing, which may be followed by most disastrous results. This is especially emphasized by the dense adhesions, and grave forms of peritonitis.

Many say these growths are very rare. Graily Hewett asserted this in 1863.[1] Terrillon in 1866 declared "Cystic fibroids of great volume were still very infrequent."[2] While Sir James Paget in 1853 said: "The formation of cysts are not rare in fibrous tumors."[3] Peaslee in 1872 wrote: "T. S. Wells assures me he meets with not more than one fibrocyst for fifty ovarian cysts. I have myself met with ten cases in the last two years, and have seen not less than fifty since my first operation in ovariotomy in 1850."[4] Pean said in 1873: "These cysts are exceedingly rare;"[5] in 1895 he said:[6] "That before 1865 Sir Spencer Wells had done 130 gastrotomies, and had found only three fibrocystic tumors of the uterus; and in 160 operations of the same kind Charles Clay had encountered only one." Pean in his statistics in 1895 tells of thirty cases of his own.

I have inquired of many of our prominent surgeons who do much work in this line, many of them have not had a case, nor could they tell me where a specimen could be found. Prof. James Ewing, pathologist to Cornell University, told me he had not a fibrocystic tumor of the uterus in the Cornell or in the Loomis Laboratory, but said that if he heard of one he would let me know. One eminent pathologist declared to me that he did not believe there was any such formation existing. I know of but one fibrocystic tumor of the uterus in any laboratory or museum in New York City, and this is given an account of in the MEDICAL RECORD, August 16, 1884, p. 177

J. Cruveilhier was one of the first to speak of these remarkable formations, saying: "The co-existence of a serous and a fibrous tumor the one and the other occupying the same cavity, is a remarkable fact."[7]

The histories of a number of cases of fibrocystic tumors of the uterus are given in "Les Bulletins de le Société Anatomique" of Paris, of which society Cruveilhier was president. This was probably the first medical society to report cases of this remarkable formation; and this society did most important scientific work in many directions. The very name of the society is well selected, and suggestive of the highest teachings; for anatomy is the source of knowledge for normal and pathological conditions. One is frequently impressed that the scientists of no nation surpass the French in their clear investigations, and their high and comprehensive pursuit of scientific truth. It was "The Famous Chirurgien Ambrose Paré,"[8] the preface of whose work bears the date of 1579, who gives the comprehensive and unexceptional definition: "Tumors against nature." What more could be said? The great pathologist Caternault, more than 200 years after, said, "Tumors of the nature fibrous are accidental productions." They are not accidental productions, they come from a fixed and specified cause; so the great pathologist of the nineteenth century does not come as near the truth as the famous surgeon of the seventeenth.

As fibrocysts of the uterus are such remarkable formations, and are comparatively rare, probably nothing will throw more light upon the subject, and show better their characteristics, their mode of formation, and their accompanying conditions than to give the histories of a few cases as narrated by different surgeons.

First a case given in Cruveilhier's great work, communicated to the society by M. Lenoir:

"The principal fibroid tumor occupied the lower portion of the uterus and was developed in the walls of this organ. A large serous cyst in the upper part of this tumor quadrupled its volume. This cyst seemed formed in the thickness of the fibrous tumor. The walls of the cyst consisted of two folds, the interior thin, resembling serous membrane, the exterior fibrous, very dense, and was continuous with the proper tissue of the uterus, of which it is perhaps a degeneration."

Pean[9] refers to a case which Cruveilhier presented before the society in 1852, more than twenty years after the preceding case:

"A voluminous cyst developing in the thickness of a fibrous tumor. This tumor was marked in its center by a cavity containing three liters of a liquid. The walls of the cyst were extremely thick and vascular."

No doubt there are many cases known only to suffering women, whose agonies were quietly endured, and whose sad histories are hidden with them in their last resting place.

In 1843 the following case of fibrocystic tumor was presented before the Anatomical Society of Paris.[10]

"A uterus, in the body of which were a great number of fibroid tumors, one especially had an enormous volume. There were eighteen punctures in the different cysts, following which the patient had peritonitis, to which she succumbed at the age

of forty-six. Upon the peritoneum which covered the tumor there were many adhesions."

M. Rieux[11] reported the history of a patient who had succumbed at the age of fifty-four in consequence of three abdominal punctures made at different times. Each of these punctures emitted a different kind of liquid; the first was sero-sanguinolent, the second was more red; the third had the appearance of dirty splenic. On the left side could be felt some hard tumors. At the autopsy there was a fibrous tumor of the uterus, a large cyst formed of two membranes which had contracted adhesions with the kidney and colon."

A most interesting case of a large fibrocystic tumor of the uterus is reported in the *London Journal of Medicine*,[12] by Prescott Hewett:

"Woman forty-seven years old, single, a large tumor, considerable fluctuation. The abdomen was tapped, and fifteen pints of thick fluid of a reddish color, and mixed toward the last with blood. Autopsy: The upper two-thirds of the tumor was composed of large membranous cyst with thin walls, the interior of which was inflamed, and filled with a quantity of dark-colored fluid. Toward the lower part the tumor was principally formed of more solid substance, and filled with an enormous number of cysts, varying from the size of a pin's head to that of a large orange. These cysts, which were lined with a thin smooth, delicate-looking membrane, were filled with a clear fluid containing a large quantity of albumin."

Washington L. Atlee gives the following case:[13]

"July, 1845, the patient noticed the tumor on the right side. It gradually increased in size, thought to be fibrous, but still ovarian. I informed the patient of the obscurity of the diagnosis, that possibly the tumor could not be removed without extirpating the uterus with it. I should not feel justified in doing that and would close the wound without further delay. May 22, 1849, operation. This brought to view a very vascular-looking tumor, large and engorged veins occupying the lower part. Several places on the peritoneal surface showed cystoform bodies filled with a yellowish fluid. Such being the case, it was considered impossible to remove the tumor."

In 1859 Mr. Baker Brown presented the following case:[14]

"From the fundus of the uterus grew a large multilocular fibrocystic tumor. The patient, aged thirty-six, had never had any children. Six years before she noticed an enlargement of the abdomen, tumor continued to increase in size. In March, 1859, was tapped, and four pints of dark fluid drawn off. Operation December 11, 1862. The tumor was so fixed it could not be removed. Mr. Brown then tapped the cyst that was first seen, and closed the wound. On the 19th of December there was a sudden burst of fluid from the central cicatrix, which evidently proceeded from the cyst that had been tapped. On the 28th of December the tumor began to refill. She gradually sank and died on the sixth of January. Post mortem. The tumor was formed of a mass of nodules, or round tumors separated from each other by large cysts in which a peculiar fluid was contained."

Mr. Fletcher reports the following:[15]

"Widow, aged forty, had five children and three miscarriages. The youngest child eight years old. On admission she presented the appearance of a person at the full period of pregnancy. Tumor movable, fluctuation distinct. Diagnosis, multilocular ovarian tumor. On May 14 the operation was performed. An incision was made five inches in length. Very firm adhesions were found on each side of the abdomen, and it required considerable force to break them down. Some cysts were punctured. It was found that the tumor sprang from the posterior surface of the uterus."

Sir Spencer Wells:[16] "The tumor was removed by a gastrotomy April 30, 1863, from a single lady aged fifty-three. It was a pedunculated growth from the right side of the fundus of the uterus, consisting of a solid fibroid mass, which weighed sixteen pounds and nine ounces, and of a large cyst, which held twenty-six pounds of fluid, and four pounds of lumpy masses of decomposed fibrin. The tumor was removed with nearly as much ease as an ovarian tumor, but the patient sank from shock four hours after the operation."

Sir Spencer Wells also gives the following most interesting narrative:[17]

"Patient forty-five years old, single. The abdomen was enormously extended, measuring fifty-six inches at the level of the umbilicus. The patient was tapped above the umbilicus, removing about thirty pints of clear viscid fluid. Fluctuation was also detected in different parts of the tumor. The tumor weighed about twenty pounds. I made an incision below the umbilicus about six inches long, and exposed what appeared to be two ovarian cysts separated by a deep fissure. I tapped the one on the left side, and about ten pints of blood serum escaped; two or three more pints of similar fluid escaped after puncturing again within the cyst first opened. The tumor was found to consist of fibrous tissue, split up in little cavities of various sizes, containing serum more or less transparent. Toward the interior extremity they seemed to be in a process of fatty degeneration, and in several places calcareous masses were discovered. In several places small blood cysts were demonstrated. The largest cyst was the size of an adult head. The body was examined after death. The tumor we did not attempt to remove consisted partly of a cyst and partly of a fibrocystic tumor. This tumor was an enormous mass eighteen inches in length and sixteen inches in breadth."

Keberle's fourth case was a fibro cystic tumor. The patient, thirty-six years old, for six years had had an abdominal tumor, which was considered ovarian; her health was good, menstruation regular. Ablation of a great part of the uterus. Death.

Now in this case, if the good doctor had done total hysterectomy, cleared out the whole, it would have been a quick and easy operation. All the cases prove that an early operation is the best way to save life.

Terrillon: "A voluminous cystic fibroid." Mrs. X., aged forty-two years, married, the mother of two children, of which the youngest is twenty years old. Seven years since she felt the growth. The abdomen gradually augmented till 1885, then it increased very rapidly, and she entered la Saltpetriere March, 1886, tumor large and fluctuating. The diagnosis given: Tumor cystic, probably ovarian, but a part solid and voluminous. Operation March 6. The abdomen opened; a tumor of the uterus, and fluctuating. It was tapped and a liter of transparent fluid flowed out. A second tumor was removed having a hard, firm consistence. The tumors were removed and the pedicle fixed in the abdominal wound. The patient made a good recovery. The case was reported in *Revue de Chirurgie*, 1886, p. 664."

Horatio R. Storer of Harvard University:[18] "Patient forty-seven years old, unmarried. A few years ago she became conscious of the existence of an abdominal tumor. This has steadily increased, and the abdomen is now larger than a woman at

full term. The patient is emaciated and cannot lie down without dyspnœa, and desires relief. The diagnosis was left undecided. Being convinced that the tumor, whatever its nature, would, if not removed, ultimately destroy the patient, I operated. An incision of five inches. The tumor was of a dark purplish color, and the omentum adherent. There were extensive adhesions to the peritoneum. There were forty tumors, ranging from two to three line to perhaps four inches in diameter; a small number of considerable size were filled with calcareous matter. There were also cystic formations that were highly vascular, some of the vessels being of very large size. The tumor was removed, and the patient made a good recovery."

Sir Spencer Wells:[10] "Fibrocystic tumor with diseased uterus and ovaries. The patient married, thirty-eight years old. The tumor had been tapped three times between 1863 and 1866, about twelve pints of fluid escaping each time. The attempt to save life by removing the tumor was made, but it was impossible to remove it. There was general chronic peritonitis, and the patient died in thirty-two hours."

R. Virchow,[10] speaking of these formations, says: "A part of the tumor is transformed into a cyst, a cyst of the wall uterine, or cystic myoma. This form which has frequently been described by English authors as tumor fibrocystic, and is most frequently with ovarian tumors (p. 395). "A woman came to consult me for a tumor which now filled the abdominal cavity. The sick one suffered greatly from the pressure exercised by the tumor. By the vaginal touch I discovered posteriorly a part that seemed fluctuating. I advised that this portion be punctured, but it was not done and the woman died some months after. One found a voluminous tumor thirty centimeters in diameter, adherent on all sides that one with difficulty could raise it out of the abdomen. I thought for a long time it was an ovarian tumor, a part solid and a part cystic."

Thomas Bryant, surgeon to Guy's Hospital:[11] "Fibrocystic disease of the uterus and both ovaries. Extirpation of the whole. Recovery. Miss M., twenty-six years old, unmarried, consulted me April, 1871, for an abdominal tumor. It was considered by the former attendant as ovarian. She was about as large as a woman in the full term of pregnancy. May 19, operation. A long incision was made, and at once the uterine nature of the growth was recognized. The tumor removed weighed eight and one-half pounds."

Fibrocystic tumor of the uterus.[12] Mrs. H., aged thirty, tumor reaching to the umbilicus, fluctuation. Abdomen opened, tumor tapped, thick, straw-colored fluid came out. Suprapubic hysterectomy. Patient died in nine days.

B. F. Baer:[13] "Patient forty-two years old, single. Her abdomen was as large as the full term of pregnancy. She had been tapped three or four times, and about two gallons of fluid removed at each tapping. There was decided fluctuation. Operation October, 1891. An incision of four inches in length showed the tumor to be universally adherent. At several parts where the tapping trocar had entered, there were strong organized bands which required ligatures. I tapped the tumor, about two gallons of fluid resembling pus escaping. The tumor was removed, the patient made a good recovery."

The most remarkable example of a fibrocystic tumor of the uterus is the one before referred to, and mentioned in the MEDICAL RECORD, August, 1884. The patient, a negro woman fifty years old, the mother of several children. The abdomen measured, at the largest circumference, 68 inches, and from the ensiform cartilage to the umbilicus 27 inches. I tapped the patient on May 6, a muddy, chocolate-colored fluid flowed. After several gallons had discharged the fluid came quite slowly, and another trocar was introduced four or five inches higher up. From this puncture came a clear, slightly amber-colored fluid. Eight gallons and seven pints of fluid were withdrawn, a considerable amount remaining, which, with the solid part of the tumor, left the abdomen still quite large. Death occurred on the sixth day after being tapped. Post-mortem. Incision through the abdominal walls and peritoneum showed a network of veins over the surface of the tumor, some of which were so large that we took them at first glance for intestines adherent to the tumor. The tumor was attached by a pedicle about an inch in diameter to the posterior portion of the fundus uteri."

The solid portion of the tumor, as stated, weighed 14 pounds. I would have been more than glad to have had a small macroscopical specimen for microscopical investigation. It would not, in the least, have diminished the value of the specimen, but it would have given a flood tide of light on the subject of fibrocystic tumors. Still, from my studies in pathology, and pathological structures, I think I can give a solution of the formation of fibrocystic tumors of the uterus as I was able to give the origin of fibroid tumors of the uterus before I made my last series of investigations; and I felt so positive of the fact that I made the assertion in the *Annals of Gynecology and Pediatry* some months preceding, and which was fully proved by my further demonstrations as presented in the MEDICAL RECORD, September 14, 1901.

Fibrocystic tumors of the uterus usually exhibit most serious conditions. The uteri which contain them, or to which they may be attached, show a more advanced stage of disease than with the ordinary fibroid tumors. They also show more serious. more complex, and more complicated pathological changes.

A few incidental remarks in the above narrations give a little insight as to the serious character of fibrocystic tumors of the uterus. Atlee says in his case: "A vascular looking tumor, large and engorged veins."

This proves active pathological processes. Fletcher remarks: "Very firm adhesions, and it required considerable force to break them down."

Firm adhesions could be formed and strengthened only by long continued and destructive inflammation. Storer says: "The tumor was deep purple, and the omentum was adherent by extensive adhesions to the peritoneum."

The conditious here mentioned show profound and chronic inflammation, and serious pelvic disease. So of Sir Spencer Wells's case, when he tells us "There was general peritonitis." Also Dr. Baer's case, "Tumor universally adherent "

We note that these tumors are almost invariably diagnosed as ovarian. Mr. Hakes said, in the *British Medical Journal*, March, 1863, that "He thought it almost impossible to diagnose in some cases between uterine and ovarian tumors." Graily Hewett says: "It seems impossible to say how they are to be distinguished." Virchow said of one of his cases: "I thought for a long time it was an ovarian tumor." In Les Bulletins de le Société Anatomique. as early as 1849, Vol. 22, page 404, we find the following: "M. Gosset showed a uterus presenting some tumors which had been taken for cysts of the ovaries. Pean reminds us that "Lizars, in 1824, was about to remove a cyst which he supposed

to be a cyst of the ovary. Seeing that it was a cyst of the uterus, he ventured no further, closed the abdomen and left it in place." Paget, in his "Pathology," Vol. II, page 138, calls attention to the difficulty of diagnosis, and says: "There is a preparation in the museum of the College of Physicians, sent by Sir Everard Home: A portion of a a uterus in which a very large encysted tumor had formed. The patient had been twice tapped, and the cyst emptied. The case, during life, was supposed to be ovarian dropsy."

Terrillon says: [24] "No special sign can differentiate this fluctuating tumor from a cyst of the ovary." Virchow says: [25] "The most part of cases known have been taken for ovarian cysts, and as such punctured; unhappily, even the punctured has almost always given a result unfavorable."

Pean declares[26] that: "Almost all the operations for tumors fibrocystic, have been accompanied first by errors of diagnosis, and afterward by non-success. It is necessary not to be astonished if a great number of this nature rest.[27] Pean continues: "One knows nothing of the fashion by which they are developed; and it is almost impossible to say what has been the point of their departure. The etiological conditions that preside at their apparition are the same as for the ordinary myoma, and are surrounded by the same obscurity."

In 1873 Pean says (p. 99): "What is the mode of formation of these cavities in the fibroid bodies? What are the laws that preside over their development? This question at the same time so interesting and so difficult, is far from being solved in spite of the numerous labors of which it has been the object."

Sir James Paget says: "The whole subject in relation to the origin of cysts needs further consideration." Terrillon also declares "The history of this affection is still very incomplete. As to the origin of cysts, one knows no satisfactory theory." Virchow says: "The anatomical characters, and the conditions that favor these morbid productions are little known. It is impossible to demonstrate the origin of each isolated tumor.[28] . . . (p. 391). The most part of cases known have been taken for ovarian cysts, and as such punctured. . . Even after they have been punctured and evacuated, they have been believed to be ovarian tumors." Schauta said, in 1890: [29] "It is to be lamented that our knowledge of the causes of this new formation, fibrocysts of the uterus, has still remained so limited."

Many theories have been given as to the origin of fibrocystic tumors of the uterus. The great surgeon, Thomas Bryant, after giving his case as mentioned on page 7, says: "The formation of the cyst was well shown to be due to fatty degeneration of the fibroid tumor."

But how can a fatty degeneration of a tumor form a cyst? How, in the first place, did the tumor have the power to change into adipose tissue?

Sir James Paget says in his pathology: "It may be due to local softening, and liquifaction of a part of the tumor, with effusion of fluid in the affected part."

But I ask this great pathologist, how can a fluid come except from a natural secretory organ; have the surrounding structures or any tissue, normally, the power to make a fluid, or have "local softening, and liquifaction?"

Right conclusions can be drawn only from a correct knowledge of pathological conditions. This eminent and distinguished pathologist, Sir James Paget, has written much that is most excellent. His pathology is one of the best. When I was in London in 1886, Sir James called to see me, probably to discuss some pathological questions. Afterward I had a most delightful visit from Sir James and Lady Paget. Just before an article of mine appeared,[30] and for a time, there in London, it caused some little discussion. Sir Spencer Wells, and a number of others spoke in regard to the paper. Subsequently, at a meeting of the London Medical Society (November 1, 1886), the paper was referred to, and quoted in a most kind and complimentary manner. The principal address on this occasion was by the great surgeon, Lawson Tait, which address was published in the *New York Medical Journal*, November, 20, 1886.

Pean says:[31] "Whatever may be the terms in which they are presented by the authors, the theories relative to the formation of these cysts in fibrous bodies are two: (1) The deliquescence of a portion of the fibroma; (2) The dilatation of the lymphatics and the formation of sinuses at the extremity of the several vessels. The first opinion was accepted by Virchow. Klebe attributed them to hydropsia and œdema."

None of these theories seem entirely satisfactory nor do they give the true explanation. "Deliquescence," according to Webster, "capable of attracting moisture from the atmosphere and becoming liquid."

Will a collection of moisture change a hard fibrous tumor to a cyst? And for dropsy, there must be some special pathological condition.

Pean states (p. 283) that "Billroth and Koeberle were the first to give the hypothesis, that at the point of departure it might be a lymphatic dilatation. This opinion has been sustained by numerous researches and demonstrations," and, says Pean, "It appears to be true for the following reasons: (1) A fibrocystic tumor resembles a lymphangioma. (2) In many fibrous tumors which we have raised, the periphery was very rich in a network of lymphatics. Some vessels dilated communicated directly with the small cysts."

Every diseased structure has a rich network of lymphatics. (See Sappey's magnificent work on the lymphatics). Pean attempts to sustain this idea by referring to the fact that "the researches of Doleris demonstrated that during pregnancy the peripheral lymphatics made some ecstasies in the fibrous bodies; and that if these productions are at the same time œdematous, the serous fluid can accumulate in the newly-formed sinuses, distend, and convert them into true cysts."

Then "serous fluid can convert lymphatics into true cysts?" Pean further attempts to prove this theory from the researches of W. Muller, that fibrocystic tumors present striking resemblances to lamphangiome cysts described by Wagner, and that, according to all probability, the mechanism of the production of the lacunes is the same in the two cases: they result from the enlargement of the lymphatics.[32]

Wise men may make theories, but the only way to learn the truth is from nature's book. Lymphatics cannot change themselves into cysts. Some of the cysts are of vast dimensions, how will the lymphatics manage? No anatomical structure can change itself into another; nor is it possible for one structure to create another, or a part of another structure. Not one of them has creative powers.

The fact that the walls of the different cysts are so different in their structure would suggest that the different cysts have different pathological conditions and that each one has a different local pathological origin. Cruveilhier in his first case, about 1828, called attention to the two folds of the wall of the cyst, the interior thin, resembling serous

membrane, the exterior fibrous and very dense." M. Lenoir said of his case, "Walls extremely thick and vascular." These differences in the walls of the cyst would not only indicate very different pathological conditions, but also very active life changes. In the first case quoted from the Bulletins of the Anatomical Society, Paris, "The cyst was formed of two membranes which had contracted adhesions with the kidneys and colon." Thus proving active pathological conditions. Another states: "A network of veins on the surface of the tumor." Again showing profound pathological changes, and also, that the membrane was in active inflammation. The case of Hewett: "Membranous cysts, with thin walls, the interior of which was inflamed."

*The fact that different kinds of fluid are found in cysts of the same tumor, would indicate again that the cysts have different pathological conditions*, and are not dilatations of the same structure. These different fluids are certainly the result of different states or conditions of the walls of the separate cysts, and of the conditions of the surrounding tissues. Thus the *different kinds of fluid in these cysts not only indicate serious and complex conditions, but that the tissues are undergoing profound life changes.*

The case of Hewett: "One cyst filled with a quantity of dark colored fluid;" other cysts "were filled with clear fluid containing a large quantity of albumin." One of Sir Spencer Wells' cases: "From one cyst removed some thirty pints of clear viscid fluid. Another cyst was tapped and ten pints of bloody serum escaped." Baker Brown's case, "four pints of dark colored fluid drawn off." The case of Virchow: "The tumor had great irregular cavities filled with bouillie infecte, all appeared to be a mass of purulent cysts." In the case reported in the MEDICAL RECORD, from one cyst, "a muddy chocolate fluid flowed;" from another cyst came "a clear amber-colored fluid."

There is but one way to explain the changes in the tissues, or how these new formations are, or can be developed; or to explain the development of any new pathological structure: And that is, *by the normal tissues being reduced to a medullary condition, and from this life material any new growth may be formed*, or any pathological structure developed.

Cysts of a fibroid tumor are formed by the tissues of the tumor being reduced to a medullary condition; and, from these primal elements, any new formation may eventuate.

Fibroid tumors of the uterus are pathological formations, and are themselves developed from abnormal conditions. Since 1900 I have been studying the structure of fibroid tumors of the uterus, many different sections of many different tumors; and, invariably, and in every instance, I have found that the tissues of the fibroid were in a profoundly diseased condition, and the structure undergoing continual changes. Again and again, I have seen the tissues reduced to a state of acute and subacute inflammation, different foci of inflammation, and repeated attacks. The structure of the tumor, in every part, in a state of pathological change. I have seen the inflammation in the tissues change to fibrous connective tissue; and this new fibrous connective tissue again breaking down into inflammation, or what is called inflammation, but what is really medullary tissue, or life material; and from this life material, or life elements, or embryonal tissue, any pathological structure may be developed.

Thus a fibroid tumor may develop within itself any growth. Life elements are unceasing in their activity, and marvellous in their products. By many distinguished authors in the past, these new formations in fibroid tumors, or, as they are called by many, "degenerations," have been mentioned. The eminent author, Amasset, in 1842, said: "The remarkable transformations of the body fibrous are well known." Caternault[33] says: A body fibrous can have a great many transformations, soft, hardening, osseous, or calcareous. In St. Thomas' Hospital, London, there are two uterine stones so hard that one has been able to saw and polish them as pieces of marble or ivory."

Bayle, in the early part of the eighteenth century, spoke of fibroid tumors being developed in the walls of the matrix, and of their ossification. Equally as early Cruveilhier, under chapter, "Maladies of the uterus," says: "Of these small tumors some were fibrous, some were osseous, in them the petrifaction was made of a multitude of points, which constituted calcareous tubercle extremely hard, disseminated in its fibrous substance very dense." In Transactions of Pathological Society, London, 1890, page 204, an account is given of some tumors removed by hysterectomy. One of these tumors was softened into areas of translucent gelatinous material. Many of these areas had broken down so much as to form myxomatous degenerative cysts. In 1890 a myofibroma, which I removed by total hysterectomy, the tumor had changed into myxomatous tissue.

Monad presented to the Anatomical Society of Paris the uterus of a woman aged thirty-three years who died three days after confinement. The fibrous tumors were very multiplied. Some were hard and voluminous; the most part were serous and infiltrated with serous fluid, and some infiltrated with blood. The deep layers of the uterus were destroyed by gangrene and softening."

When the tissues of a uterus, or of a fibroid tumor are reduced to medullary tissue, any structure may be developed in either of them, *and so pus may be formed*. Virchow says:[34] "The work of ulceration is complex in theory." So it is. Robert Lee tells of a patient who consulted him in 1843. Upon opening the uterus after death there flowed out a quantity of fetid pus. The whole lining membrane of the uterus was inflamed, and near the surface, appeared softened and disorganized.[35] Dance[36] reports the history of a woman forty-two years of age who died of peritonitis; at the autopsy the womb was found to be enlarged, and in the anterior wall a purulent formation which contained eight or ten ounces of pus. Boscredon (tome XXIX) tells of an abscess found in the center of a uterine fibroid tumor. No doubt an abscess often exists in these tumors, though not recognized; for when the tissuesof a tumor are reduced to a medullary condition any new formation may be developed, calcareous or osseous, fatty degeneration, or the formation of pus. Any pathological structure may come from these medullary elements.

We now enter the secret laboratory of nature. Who can explain? In 1888 (*New York Medical Journal*, August 25) I spoke of cancer being developed in a fibroid tumor. This growth may come as naturally from the medullary material of a fibroid tumor as may come any other growth. Bayle speaks of cancer of the matrix, and alleges that "It is a degeneration of these tumors." Is it not rather a new development from the life elements, or from the medullary material? Before the New York State Medical Society, January, 1901, I presented the origin and formation of cancer, saying: "That whatever might be the microbes or germs, that for the development of cancer, the tissues must

be reduced to a medullary condition, or to their life elements. These are the anatomical and pathological processes. I have read them again and again in nature's book, which Harvey says is open and legible."

Virchow declares: "The theory of the transformation of fibrous tumors into cancer rests still in confusion. It can only be a question if by exception a myoma can become cancerous."

FIG. 1.—A fibrocyst of a fibrous tumor of the uterus; *w*, *w*, cyst wall; *i*, *i*, *i*, fields of inflammatory corpuscles showing intense inflammation; *c*, *c*, *c*, cystic canals in process of formation.

A myoma when reduced to medullary or life material, or to their primal elements, may form any growth or develop any pathological formation. It is thus that osseous or calcareous tumors are formed. In the same way pus or cancer may be developed. As I have found in every fibroid tumor I ever examined microscopically, it was in a state of disease and changing pathological conditions; and, from the medullary or life material, new formations were continually being produced. The new formation may be only fibrous connective tissue, or it may be pus, or it may be cancer. This life material is in a constant state of activity, and endless in its possibilities; and from it may be developed any pathological new formation.

*It is thus that fibrocysts are formed in fibroid tumors, or in diseased uteri.* The tissues of the fibroid tumor, or of the uterus become reduced to their life elements, and, from these life elements or medullary material, a cyst may develop.

It is in the same way that ovarian cysts are formed. One of my first observations in the study of the pathology of the ovaries, was "*the line of inflammation around every small cyst.* I thought at first this was only an indication of the very diseased condition of the organ." I also said in the *New York Medical Journal*, September 28, 1889: "In one ovary there were small cysts, the walls of which were formed by stratified layers of inflammatory tissue. In the microscopical study of the ovaries I have frequently found these small cysts, and never have seen one but it was surrounded by newly-formed layers of inflammatory tissue, and frequently layers of secondary fibrous connective tissue, the latter indicating long existing disease. The small cysts have a history of suffering; they are either the outcome of inflammation, or have produced the inflammation." I did not know how near I was to the truth in saying, "they were the outcome of the inflammation." I said in the *American Journal of Obstetrics*:[37] "I could see again and again the intense inflammation in the cyst wall and in every instance when the cyst wall was thus inflamed it was separating, crumbling, and the parts passing into the cyst fluid. The cyst was increasing in size, and the intense inflammation of the adjoining tissues showed that it would grow yet larger. Any tissue of the ovary, any structure, can become inflamed; and in any tissue, or in any structure in which inflammation exists a cyst may be developed. This is the beginning and the origin of ovarian cysts, and the only condition that can produce a cyst of any nature. There is first inflammation, the tissues reduced to an embryonal condition, and then the new growth, the cyst formation."[38]

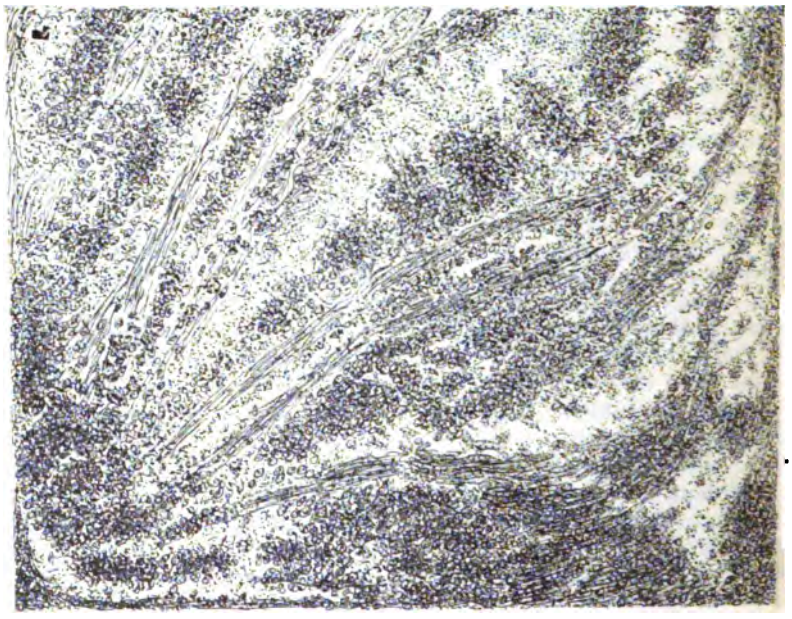

FIG. 2.—Another section of a fibrocyst of a fibroid tumor of theuterus; *i*, *i*, *i*, fields of inflammatory corpusles; *c*, *c*, *c*, cystic canals.

Nature's plans are always simple and beautiful, and always according to the same fixed laws. When, in 1901, I said that for the formation of a fibroid tumor the tissues of the uterus must be reduced to a medullary condition, I was only saying what I read in nature's book, and it was repeatedly presented and proved. The conclusion spoke for itself. I saw it so clearly that I said in the *Annals of Gynecology and Pediatry*, April, 1901, page 460:

"Fibroid tumors are diseased products and the result of diseased conditions. They can develop or be produced only by the tissues of the uterus being more or less inflamed, or reduced to inflammatory corpuscles, or to a medullary condition. Only in this way can any new growth be developed, or can the uterus give origin to fibroid tumors."

But even after this I wanted to be still more assured. Up to that time I had studied principally

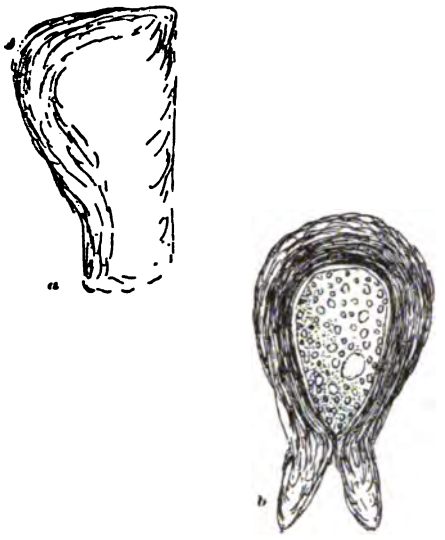

Fig. 3.—*a*, Half section of the uterus; *b*, section through the organ showing the tumor.

my own specimens of fibroid tumors which I had removed by suprapubic, or total hysterectomy; so I wanted the great fact still further confirmed by the specimens of others. It was at that time that Prof. W. M. Polk gave me a letter to Prof. James Ewing of Cornell University, who kindly took me through the Cornell and Loomis laboratories, giving me a macroscopical specimen of any tumor I might select. All these I prepared according to the best methods. These sections of the uterus near the fibroid tumors, enclosing a portion of the tumors, I studied most carefully; all confirming and giving most beautiful illustrations of the same. But as I then said, I did not feel more convinced; but it was an added authority to make the statements, as I did in the MEDICAL RECORD of September 14, 1901.

I wanted to know the truth. If I was wrong I wanted to see my mistake; but all confirmed me in the great truth which I read in nature's book.

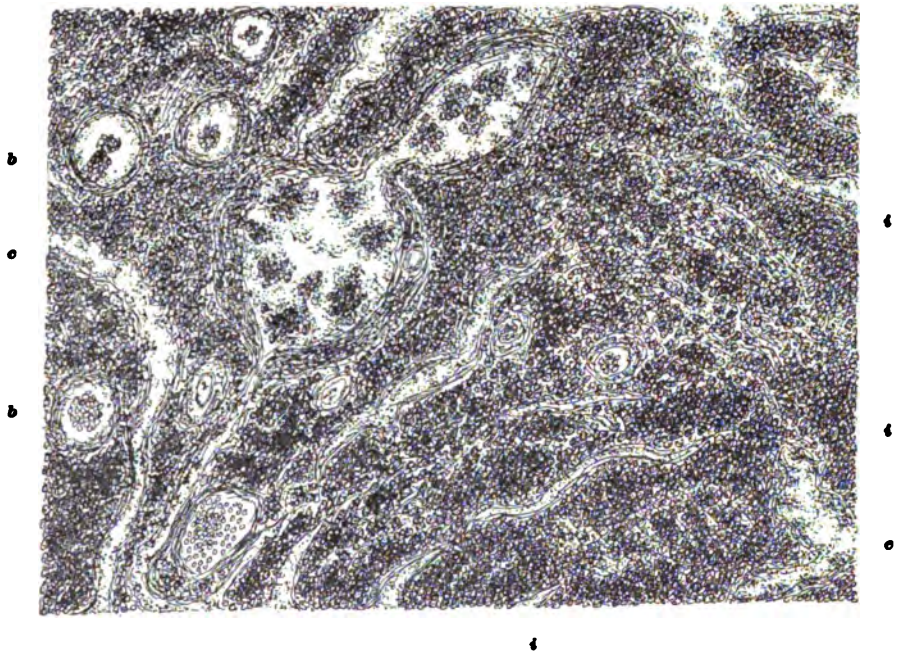

Fig. 4.—Section of a uterine tumor; *i*, *i*, *i*, inflammation; *c*, *c*, *c*, *c*, fibrocysts; *b*, *b*, *b*, blood vessels.

Thus in this paper, I have spoken of the pathological changes that may take place in fibroid tumors of the uterus, how they may be reduced to medullary material, and from these life elements may be developed any new growth.

In the same way, the uterus, when diseased, when by inflammation the tissues are reduced to a medullary condition, fibroid tumors themselves may be developed. This great fact was presented again and again.

At the meeting of the Academy of Medicine, Section of Obstetrics, April, 1903, an eminent surgeon remarked, that "Fibroid tumors caused degenerations of the uterus." This is not according to the teachings of pathology. It is from a diseased condition of the uterus that fibroid tumors are developed. Fibroid tumors do not cause the disease, but it is the existing disease of the uterus that causes the fibroid tumors. From the same disease of the uterus, cancer or carcinoma may be developed in the cervix or in any part of the uterus. So the eminent surgeon, Prof. W. M. Polk was perfectly correct in questioning whether carcinoma or cancer of any part of the uterus was directly dependent upon a fibroid of the uterus.

A fibroid tumor of the uterus does not, and cannot produce a cancer of the cervix, or in any part of the uterus. It is disease of the uterus that causes the development of a fibroid; so it is disease of the uterus that causes the growth of cancer or carcinoma.

Two other surgeons at this meeting remarked that fibroid tumors caused disease of the ovaries, one saying: "A great many diseases of the adnexa are really due to the presence of fibroids." The other remarked that, "Degenerative changes of the ovaries and tubes were undoubtedly caused by fibroids or fibromyomata."

It happened that immediately after the addresses of the last two surgeons, the chairman invited me to speak. I made the emphatic statement that fibroid tumors of the uterus did not cause disease of the "adnexa"; but that it was the disease of the uterus that infected these organs and caused them, the tubes and the ovaries, to be diseased.

I remarked further that Koeberle, in reporting his cases of the removal of fibroid tumors, repeatedly said "the ovaries were perfectly healthy." The ovaries are never perfectly healthy when there is fibromyoma of the uterus. The disease of the uterus, that caused the fibroid tumor, infects the uterine appendages and necessarily caused them to be diseased, sometimes most profoundly. In 1888 I asserted that in case of a fibroid tumor of the uterus the uterine appendages were always diseased. I also then said: The fibroid tumor could not have produced the disease of the appendages." Still the disease of the tubes and ovaries might be so great

that if there were no other, more direct, and immediate source of infection, they might cause disease of the uterus, which disease might produce a fibroid tumor.

I also, in 1888, said that when there was a fibroid tumor of the uterus, the cervix was also

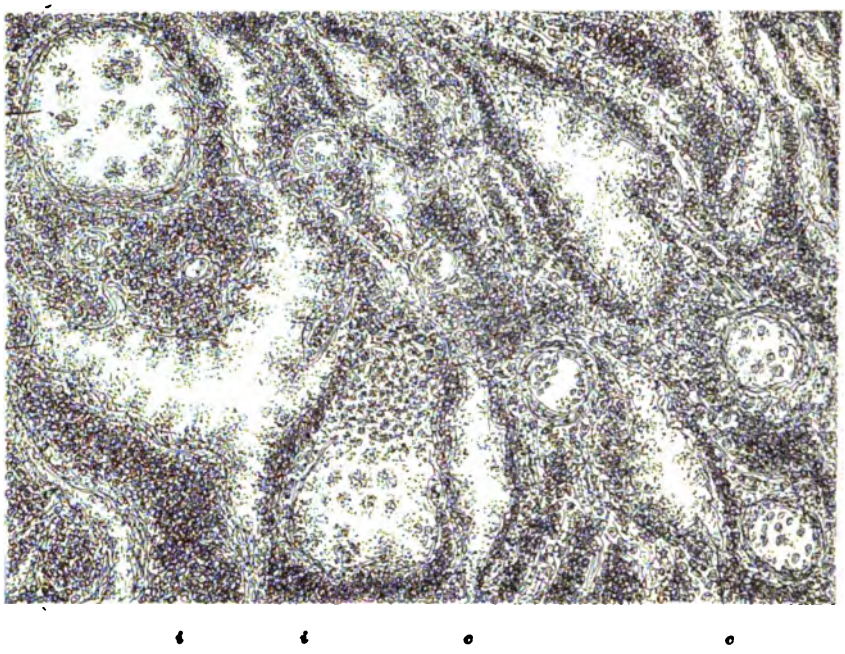

FIG. 5.—Section of uterine tumor showing fibrocystic formations; *i*, *i*, *i* inflammatory corpuscles; *c*, *c*, *c*, *c*, *c*, fibrocysts of a fibroid tumor.

diseased, often the most diseased portion of the organ, as I then called it, "The remnant or remains of a sickly womb."[1] And now I say that, in justice to the patient, this diseased "remnant" should not be left in intra- or extraperitoneal treatment.

Certain assertions in regard to fibrocystic tumors of the uterus in this paper were made before I had ever examined or even seen a specimen of the formation. Lately a portion of a fibrocystic tumor of the uterus has been sent to me by Dr. Simon Flexner from the laboratory of the University of Pennsylvania. The following history was given: "M. W., thirty-four years old, married six years, one child, forceps delivery. Symptoms began four years before admission into the hospital, usual one of fibroid. Uterus was not removed; tumor was subperitoneal and pedunculated. It contained a fluid of a dirty yellow color, turbid and specific gravity about 1024."

In this specimen, I noted first that the cyst wall was firmly adherent to the tumor, showing a state of intense inflammation.

I had the specimen prepared according to what I consider the best methods; and sections were made of it in the laboratory of Cornell University. I mounted the same, and the thorough examination of these sections by the microscope more and more convinced me that my assertions in regard to the pathology and etiology of fibrocystic tumors was the true theory. The peculiar shape of the fibroid cysts was a marvel. Ovarian cysts are round; and, as accurately pictured in the *American Journal of Obstetrics*, April, 1901, "the medullary tissue was breaking down and forming cysts."

*The fibrocysts of uterine tumors, or of the uteri, are formed on the same principles*, viz., by the tissues of the tumor, or of the uterus being reduced to medullary material and forming, not always round cysts, but more frequently irregular cavities, or canal-like formations. Sir Spencer Wells calls them "Small cavities of various sizes." So any appearance should be accurately described, though at the time it may seem a little incongruous. More knowledge will give increased light. In all the plates or drawings I have at any time utilized, there has been given as nearly as possible a correct presentation of the special tissues as seen under the microscope. But who can copy all the marvels, or picture the fine and exquisite workmanship? Even photography often makes only a bright blur without any clear definition.

Fig. 1. A representation of a section of a fibrocyst in a fibroid tumor of the uterus. The structure of the wall of the cyst is surpassingly beautiful; there is the lace work of the fine granules, and there is the crowding of the bright round inflammatory corpuscles, which do such wonderful work in all patho-

FIG. 6.—A section of the fundus of the uterus; *p*, peritoneal layers; *i*, *i*, *i*, inflammatory corpuscles; *c*, *c*, *c*, cystic canals; *b*, blood vessels.

logical formations. The tissues of the tumor are in a most remarkable manner reduced to inflammatory corpuscles or medullary material. The fields of inflammatory corpuscles are in great numbers, and in many places increasing and spreading. A few remnants of muscle fibers are seen, and in every part are unnumbered granules. The granules or life elements have great powers and possibilities; and

each one is of wonderful and of unknown structure. They do marvellous work, but no one can tell their mode of operation, or how they have the power to form, in one case fibrocystic canals, in another hard fibrous tumors, in another osseous formations, and in another pus. These are mysteries past finding out. "As thou knowest not what is the way of the spirit, nor how the bones do grow in the womb of her that is with child: even so thou knowest not the works of God who maketh all."—Eccl. XI-5.

Fig. 2. Another section of the fibrocystic tumor of the uterus. Fields of intense inflammation, in many places approaching suppuration. On the walls of the cyst canals are many muscular and connective tissue fibers. The granular material show active operations and changing pathological processes. All the tissues of the tumor are wonderfully reduced to their primal elements, and are separating in various directions, forming long cystic canals, or irregular cavities. In many sections, by a power of 400, the tissues of the tumor remind one of great pieces of timber broken asunder by some unseen power. Here the tissues are separating, making many canals

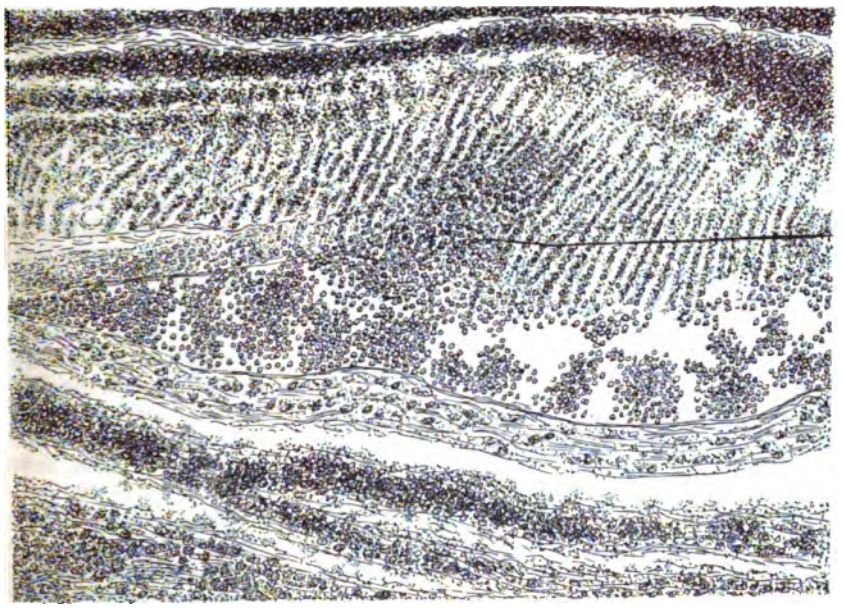

Fig. 7.—Fibrocysts and a blood cyst of the uterus; *i*, *i*, layers of inflammatory corpuscles separated by a canal cyst at *c*; *g*, *g*, granular material separating and forming a cyst; *g'*, granular material forming granular canals in which are developing blood corpuscles; *a*, blood cyst; *w*, wall of blood cyst; *i'*, *i'*, inflammatory corpuscles separating and forming a fibrocyst, *c'*.

and all are progressing toward the formation of one immense cyst. The powers of the life elements are marvellous. In this plate or presentation we can read almost the whole history: First, the normal tissues have disappeared; then, are the inflammatory corpuscles, and the granules; after come the forming cysts. As Harvey says, "Nature's book is legible.'

While the canal formations seem to predominate, yet in the same sections appear a few round cysts.

*A Remarkable Example of a Fibrocystic Tumor of the Uterus.*—Some months ago, through Cornell University, were brought to me from the morgue, the uterus and adnexa, said to be of a woman seventy-one years of age; but the specimen had the appearance of organs as seen in the flush and vigor of young sexual life. One could even imagine the specimen representated the first month of gestation. I concluded there was some mistake so I left the specimen quietly in its preservative fluid.

Fortunately, a few days since, I thought I would examine this uterus. I made an incision through its length, the cavity of the uterus was somewhat enlarged and filled by a tumor one and a half inches long, the upper part three-fourths of an inch wide and tapering to a point.

Fig. 3. The tumor had the appearance of a malignant growth, yet there were in it many apparently small cysts. I prepared the specimens, and sections were made in the laboratory of Cornell University. I mounted these specimens, and, under the microscope the revelations were marvellous. The uterus in every part exhibited a state of most intense inflammation, not the least vestige of normal tissue, but all making a wonderful presentation of *fibrocystic growths*. In the midst of the inflammatory material were forming many irregular cystic cavities, or cystic canals. It was a perfect sea of devastation. Where there is a fibrocystic tumor of the uterus, there is always a vast amount of disease. *Only a profoundly diseased condition of the tissues can produce one of these formations.*

The tumor formed within the uterus, proved to be a fibroid tumor, and, under the microscope, all the tissues of the tumor were in a state of intense inflammation, and everywhere forming fibrocysts.

Fig. 4. Immense fields of inflammation. Such are presented in every part. Inflammation must exist before there can be any new formation. Inflammation is caused by some sepsis or disease; and, by wise principles of nature, this inflammatory material is reduced to primal elements, from which are developed these formations. As beautiful as they are, they are all the products of disease, and all show continually new pathological changes. Where the inflammation is the most active, there begins the formation of the new growth. If there was no inflammation or disease there would be none of these abnormal growths. As I said in 1901[1]: "The rapidity of their growth is owing to the different degrees of inflammation and infection that may exist in each individual case."

Fig. 5. A more advanced stage of the formation of these fibrocysts. We see the surrounding inflammation and the enlarging cysts.

One cannot look into these marvellous changes and new formations without a worshipful awe, and a reverence for the Infinite Power, and the Divine Beneficence displayed. By these wonderful pathological processes and life changes, the system is often saved from an overpowering destruction. For, when tissues are reduced to medullary material, or to their primal elements, as the result of infection, or some septic disease, *pus may result, or be developed apparently as easily and as naturally as any other pathological formation.* But, if pus comes!—there can be no more of these beautiful formations and indescribable pictures of dazzling beauty. Pus is death to the tissues; there will be no more life activities; and pus thus formed may carry death to the whole system.

All the specimens of fibrocystic tumors thus far considered, prove more and more all that I asserted in the first chapter in regard to the cause and origin of fibrocystic tumors of the uterus. They also give confirmation, and yet more increased light on the

great principles as to the origin and formation of fibroid tumors of the uterus,[42] of the origin and formation of ovarian cysts;[43] and of the vast pathological changes that I have called attention to in diseased ovaries;[44] and the more wonderful revelations in regard to diseased ova.[45]

I will now speak of this uterus. All the instances of fibrocystic tumors which I have referred to as given by different authors, not one of them was of the uterus; but all of them of fibroid tumors. Cruveilhier says: "A large serous cyst in the upper part of the tumor." Pean says: "A voluminous cyst in the thickness of a fibroid tumor." Prescott Hewett, "The upper two-thirds of the tumor was composed of a large membranous cyst." Atlee speaks only of the "Vascular-looking tumor." Fletcher, "The tumor sprang from the posterior surface of the uterus." Spencer Wells, "Fluctuation was detected in different parts of the tumor." Terrillon says: "Tumor cystic." Storer, "Tumor was of a dark purplish color." Virchow, "A part of the tumor is transformed into a cyst." Bryant says: "The tumor removed weighed eight and one-half pounds." In the case reported in the MEDICAL RECORD, 1884: "The tumor was attached by a pedicle to the posterior portion of the fundus."

I have examined over twenty volumes of "Les Bulletins de le Société Anatomique," and found no record of a fibrocyst in the tissues of the uterus.

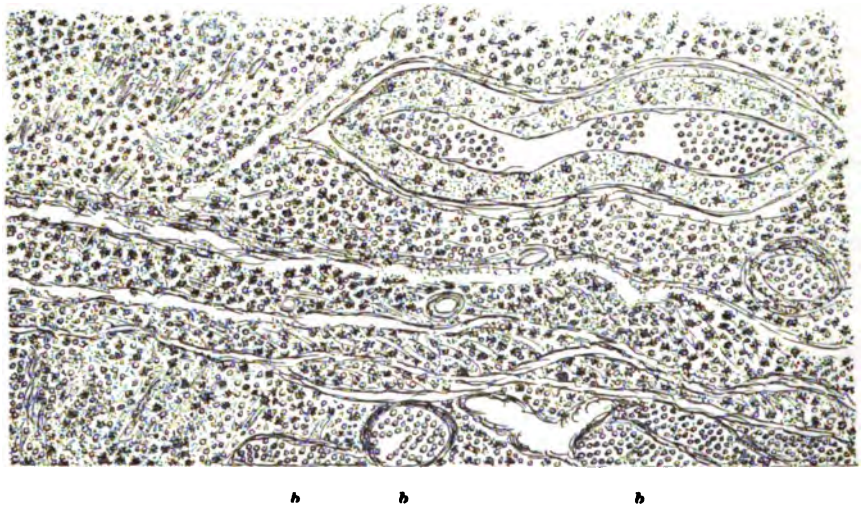

FIG. 8.—*g, g, g, g,* Groups of granules from inflammatory corpuscles; in the same field are scattered blood corpuscles; *c, c, c, c,* canal cysts; *b, b, b, b,* blood cysts.

Pean, in 1873, says;[46] "Tumor composed of two parts, one fibrous and the other cystic;" and in his great work[47] repeats: "These cysts in fibrous bodies." This same accurate observer, on page 294, speaks of cysts in the uterus, but on page 297 says: "In the ten cases which I have mentioned a portion more or less considerable of the tumor was enclosed in the uterine."

So from this, these fibrocysts *were of the tumor, and not in the tissues of the uterus.* In this specimen we have clearly presented a *fibrocyst of the uterus.* Thus this proves to be a most remarkable specimen, and one of exceeding interest and value. Pean says "There scarcely exist three or four examples in science." The whole organ was in a state of intense inflammation, and, in this inflamed tissue were developing numerous cystic canals. No uterus I have ever seen under the microscope exhibited such an *entire destruction of normal tissue, such serious disease, or such profound pathological conditions.*

Fig. 6. A section of the fundus of the uterus. We see the intense inflammation and the forming of many cystic canals. The peritoneal layer is reduced to granular material (1), and to inflammatory corpuscles (2). But what is more remarkable *everywhere in the tissue of the uterus are being developed blood corpuscles,* as if the whole structure was to be reduced to blood cysts. The light central portion may be the beginning of such a formation. In 1889, in studying "Endothelioma of the ovary," I demonstrated by repeated examinations the formation of blood corpuscles. I said I could clearly see that the protoplasmic bodies seemed to round themselves, the coarse granules wonderfully shaping themselves into blood corpuscles.[48] Many regard what we call a hæmatoma as an effusion of blood. It is not. It is a pathological formation of blood corpuscles.

Fig. 7. A blood cyst in the wall of the uterus. In this section there were forming many large and small blood cysts of various shapes. Wells said of one of his cases: "Small blood cysts were demonstrated." But here under the microscope were some blood cysts apparently of immense size speeding their way through the tissues.

In this figure we can read a history from nature of the formation of blood cysts. At the upper part are two small portions of a wide layer of inflammatory corpuscles. This is the first stage, the origin, and the beginning of the formation of a cyst. This is the only way cystic canals, or any other cysts, can be formed, viz., by the tissues being reduced to medullary or life material, or to their primal elements; and from these any pathological growth may be developed.

These two portions of inflammatory tissue, I, I, are changing into, and forming a long cystic canal, C.

Next, at G, G, we find the tissues still more reduced to their primal elements, or to granular material. This layer of granules is also developing a canal cyst.

Then comes the large layer of granular material, G, mysteriously forming granular canals; and, in these granular canals are developing blood corpuscles. What a revelation! We are looking into the secret laboratory of nature.

At B, the blood corpuscles are apparently most rapidly forming and increasing the size of the cyst.

Below the wall of the blood cyst is a fibrocystic canal, C, then a layer of inflammatory corpuscles, I, I, developing toward the right a fibrocystic canal, C. In all the portions of inflamed tissue are appearing blood corpuscles. All the tissues are thus changing and every part of the uterus seems to be forming blood cysts.

These are most remarkable changes and all the result of disease, all the sequel of some sepsis.

But now comes the most interesting and wonderful part, which I have recognized only since examining the last few sections. For more than twenty years I have been studying pathological tissues by high and low powers of the microscope. I could speak of inflammatory corpuscles and little granules, but did not certainly know the relation of these two kinds of mysterious bodies. I knew they were both developed in the process of the tissues being reduced to medullary, embryonal, or life material.

This pathological specimen, or this diseased uterus, reveals the point. It presents a most

markable demonstration in regard to the formation of granules. At A. A, A, A, Figs. 8 and 9, we see clearly that each inflammatory corpuscle is changed to a mass of granules, retaining for awhile the shape and the size of the original corpuscle. This is a most interesting fact. No one, as far as I know, has ever mentioned it, but here is the plain presentation. So important did this seem to be that I had drawings made from different parts of the tissues, all demonstrating the same point. Everywhere the great truth was substantiated, thus it was from the inflammatory corpuscles that the granules or life elements were derived. The *inflammatory corpuscles are the results of changed normal tissue*, or they are *the remains of normal tissues. In them are the life elements of the original tissues; and these vital elements are ready for the development of any new pathological formation.* Here, in the midst of the granules or life elements, are being developed blood corpuscles. If it had happened that the section had passed horizontally through the granular canals as represented in Fig. 7, we would have had exactly this presentation. In Fig. 6 the blood corpuscles are forming amid the granular canals. Here they are forming in the same way amid the granules, and, according to the general principle, they are more abundant where there has been the most intense inflammation. Everywhere the light of these little round bodies are appearing; everywhere are the shadows of the coming blood corpuscles; a multitude shimmering through the granular material and the remains of the inflammatory corpuscles. In some fields almost a firmament of these little stars appear. Apparently *the whole uterus is thus making the remarkable demonstration of changing into blood corpuscles, and forming a blood cyst.*

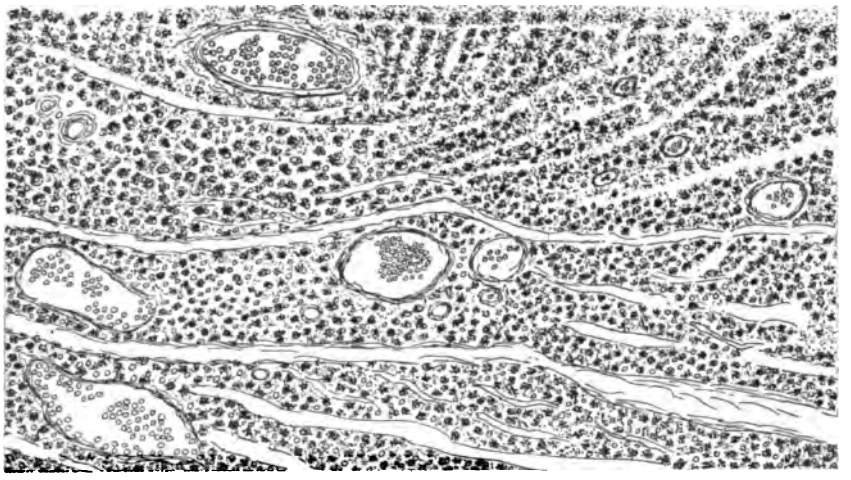

FIG. 9.—*g, g*, Groups of granules from inflammatory corpuscles; in the same field are scattered a few blood corpuscles; *c, c, c, c, c*, canal cysts; *b, b*, blood cysts.

At Fig. 8 we see repeated illustrations of the mass of granules developed from the inflammatory corpuscles, and these masses of granules are forming blood corpuscles. It is represented in all the tissues; and the new forming cysts are spreading and increasing, showing again how all the tissues may be reduced to one immense blood cyst.

The great scientist, Virchow,[49] gives the opinion, that "the liquid of fibrocystic tumors results from softening (ramollissement) of the tissues; and the liquid is almost colorless, or slightly tinted yellow, or more frequently like synovia. Subsequently, and especially in large intraperitoneal tumors, the vessels are greatly dilated and congested; there is a true extravasation of blood, and the liquid presents a red coloration, or brownish red, yellow brown, or dark brown, according as the blood is extravasated a longer or a shorter time, and accordingly mixed more or less with the rest of the liquid."

I cannot see that the blood is an extravasation from the blood vessels. I think we can clearly read here in Nature's book the origin of the blood. If there was an extravasation from the blood vessels, where would it end?

But, if possible, a yet more important fact is presented: That in the formation of blood corpuscles, as here revealed, is given *the method of the beginning and the formation of any pathological growth or formation.* This is clearly taught. It is a wonderful revelation and cannot be too carefully considered.

This mass of material, inflammatory corpuscles and granules, have frequently been denominated "inflammatory infiltration." Is not this covering up great facts by an indefinite expression? In this so-called "inflammatory infiltration" there are many anatomical elements which should be well differentiated. They are active life material, and this life material is continually making rapid progress, or some new pathological change. It is in the midst of such that any new growth may be developed. Here we see it developing into blood corpuscles. It was in such a scene, or in the midst of such life elements or life material, that I first recognized the development of cancer. There were the inflammatory corpuscles, and the granules. I saw that from the inflammatory corpuscles cancer epithelia were being developed. In this way, and on these principles, any new growth may be developed.

When I first recognized the development of cancer from inflammatory corpuscles I was working in Dr. Charles Heitzman's laboratory. He was an eminent pathologist, but in nothing did he show his great teaching abilities more than in allowing the various students to pursue his or her own investigations. It was thus after much study and research in many microscopical preparations that I saw this great fact. I saw it so clearly that I said to the master of the laboratory: "These inflammatory corpuscles are changing to cancer epithelia." "You are mistaken." So I rejected all my conclusions and went over the whole ground again. Seeing the great fact repeatedly presented and proved, and being yet more convinced, I again said, "These inflammatory corpuscles are changing to cancer epithelia." "Impossible." He was still busy with pupils. Again I rejected my conclusions, again going over the ground, seeing the facts again demonstrated, I said still more positively, "These inflammatory corpuscles are changing to cancer epithelia." He replied something about Virchow. But Nature's book is greater than Virchow, and from it we will have yet greater revelations.

On the authority of these facts, and these pathological principles, I am ready to repeat the great truth, as I asserted in regard to fibroid tumors of the uterus, that all abnormal growths are in a patho-

logical condition, and in a state of change; and, they are continually progressing to more serious and unexpected developments.

We have seen from the inflammatory conditions of the tissues of uterine fibroids, various diseased products have been noted by many great scholars. *In the same manner cancer formations are in a state of inflammatory change, developing and progressing to new and more serious pathological states, and to more serious manifestations.* We see cancer epithelia breaking down into a medullary condition, and developing more virulent forms of disease and more dangerous products. Once I removed a carcinoma from the floor of the pelvis,[50] the mass was found to consist of a scirrhous, an adenoid, and a medullary portion; so the first formation was progressing to more and greater malignancy.

All abnormal growths are continually in a state of change, and are becoming more and more complicated in their conditions. This sustains what I have asserted in regard to fibroid tumors, that the sooner a fibroid tumor of the uterus is removed the better for the patient, and may, as I said, save a long history of suffering.

Nature, in her infinite resources, makes beautiful revelations of the diseased conditions of abnormal growths. But there is nothing like the infinite perfection of normal structure.

By proper care these diseases and complications may be avoided. Even as regards cancer, though it may have hereditary tendencies, yet by attention to the simple principles of the laws of health, there is a way it may be prevented. I hold it to be one of our first duties as physicians, to teach somewhat the laws of health, and especially to mothers. To each one of them is said, "Take this child and nurse it."[51] How can she do her whole duty unless she knows something of its physical organization?

## COPPER IN SYPHILIS.

BY A. F. PRICE, M.D.,
MEDICAL DIRECTOR, U. S. NAVY.

THE baleful influence that syphilis exerts over the individual and his descendants is being more fully realized every year, but it is doubtful whether a complete and rounded view of the disease is yet attained.

We know of its influence in causing tabes dorsalis and paralytic dementia. But it is not so well known although of equal importance, that endarteritis causes an almost infinite variety of disorders. In the delicate lining membrane of the arterial system is distorted, through hyperplasia of the connective tissue, there may be caused, not only the gross lesions of aneurysm and valvular heart disease, but also insanity, a variety of spinal disorders, degeneration of the heart muscle, and, in fact, impairment of function of any and every organ in the body.

There is also a cachexia or condition of bad health which is not infrequently shown by old syphilitics in which there are no focal lesions, and which is manifested by weakness. The patient feels below par, he has no endurance, is void of energy and is constantly complaining.

These symptoms, as well as the conditions known as parasyphilitic, appear frequently enough at a time when a man has forgotten a mild syphilis from which he suffered in his youth; and he is loath to believe that his present ills are due to that cause.

Whether syphilis is curable is doubtful; but the experience of thirty-five years in the treatment of cases of this disease in the Navy has brought the conviction that the use of copper is of value as an addition to the accepted treatment, and it has some peculiarities that are of great interest and command attention.

The most important of these is an intolerance of the copper salt, which, when it exists, is characteristic of old syphilis. A case that I have now under treatment will give an idea of this reaction.

I was called about three months ago to a patient aged forty-four years who was suffering with a sharp stomach crisis. He had been having these attacks about once in ten days for a year. They lasted from twenty-four to thirty-six hours; were accompanied with severe pain and prostration, and, at the termination, with vomiting. He suffered also with confusion of mind on awakening in the morning and

with blindness at this time lasting for a few seconds. He swayed with eyes closed and his patellar reflexes were exaggerated. He is married and he lost his first two children, and has a child now five years old. He denies syphilis positively. He was given a tablet of $\frac{1}{3200}$ gr. arsenite of copper thrice daily, with instructions to increase regularly the number taken. When taking five at a dose, about $\frac{1}{600}$ gr., he complained that the medicine made him weak so that he could not perform his duties with his usual ease. The medicine was, however, continued, in the form of copper sulphate, and carefully increased until he was taking a dose thrice daily of gr. $\frac{1}{60}$. This was reached after about three months' treatment, when one-half a grain of blue mass was added to each pill.

This medication has already produced a surprising effect. He had no attack of stomach trouble for twenty-eight days after he was put on the minute copper doses, and the attack then was milder and shorter in duration. Each succeeding attack has been progressively lighter, although he has had them at intervals of about a month. But they are already shorn of their terrors, and his head symptoms are much ameliorated. I have no doubt of his continued improvement.

The intolerance of copper is frequently more marked than in this case.

For convenience, a tablet of copper arsenite of gr. $\frac{1}{200}$, issued by the Medical Department of the Navy, is used at the beginning of the treatment of cases of old syphilis; and frequently it cannot be borne. A half one or one-quarter, or even less, once a day, will sometimes cause feelings of prostration and almost collapse. As far as my observation goes there exists no other disease in which this sensitiveness to copper exists. It is therefore a valuable diagnostic aid. After a dose of about $\frac{1}{600}$ gr. is reached the copper sulphate is usually given, made up into a pill with extract of gentian.

I have one other mild case under treatment at present which is of interest. This patient is forty-eight years of age; a portly and vigorous looking man. He had syphilis of a mild character sixteen years ago. About two months ago he complained of lack of propulsive power in his bladder, which had been troubling him for several months. An examination of the urethra and bladder discovered no cause for the condition. His history being known, further examination revealed the Romberg symptom and a sluggish patellar reflex. The usual commencing dose of copper arsenite developed a somewhat greater sensitiveness to copper than the previous case. After one month of increasing doses, when he was taking about $\frac{1}{600}$ gr. of copper sulphate, he suffered with constipation and a feeling of constriction in the hepatic region. This treatment was therefore temporarily suspended and a podophyllin laxative with one-half grain of calomel was given at night and followed in the morning by the Carlsbad sual. This was given daily for a week, when the condition being relieved, the original treatment was resumed and pushed so that at the end of two months the patient was taking the same blue mass and copper sulphate pill given in the first case. The bladder symptoms have disappeared and his prospects are very good.

A number of cases of tabes dorsalis of syphilitic origin have been under my care in various stages and in none of them has the copper treatment failed of benefit. It is of the utmost importance in these degenerative manifestations of syphilis (called parasyphilitic) to establish speedily a tolerance of copper, as in doing so an increased vital resistance is developed, which is the first step in the improvement of these sad and often hopeless cases.

The following is a case of syphilitic cachexia without focal lesions: A corpulent gentleman about fifty years of age suffered with ill health and persistent swelling and tenderness of the feet. He had been treated for rheumatism, gout, and anæmia by various medical advisers, of which he had many at various times, and frequently several at once. A careful summing up of his case by one of his doctors was handed to me by the patient on his coming under my care, and was about as follows: The patient is in the early stage of hyperplasia of the connective tissues of both liver and kidneys; his heart, which has probably been hypertrophied, is showing signs of dilatation; his blood is deficient in hæmoglobin; the urea is markedly diminished, at times being as low as 221 gr. a day, and the quantity of urine is frequently below normal.

From a journey to a celebrated doctor of a neighboring city he brought back a diagnosis of erythromelalgia, which, indeed, described very well the condition of his feet. The patient was a bachelor. He emphatically denied having had syphilis, but his statement was rendered doubtful by the existence of the lymphatic enlargements common to the disease, and, as shown by a test dose of arsenite of copper ($\frac{1}{3200}$ gr.), the existence of an acute susceptibility to this drug.

It took much care and patience gradually to bring this patient to taking increasing doses of the drug. When a dose of gr. $\frac{1}{500}$ copper sulphate had been reached there appeared an obstinate constipation which did not yield to the laxatives on which he had been depending, such as cascara, podophyllin, sodic phosphate, natural purgative waters, etc., and as this patient was unfortunately one of those who knows more than his doctor, he could not be induced to take even the small dose of calomel ordered. In his opinion he was too weak for treatment by this drug, and here my connection with an interesting and promising case came to an end.

While this patient was taking his minute doses of copper the secretion of urea increased steadily in amount until it passed the normal and reached a total in one day of 667 gr.

A very acute case of tabes came under my care at the Naval Hospital, Washington, D.,C., in June, 1900. A young man aged twenty-seven years contracted syphilis in the West Indies in January, 1899, and was treated for the secondary symptoms in March following. In May of the following year symptoms of tabes developed. The symptoms gradually increased in severity for about six weeks, when he could no longer attend to his duties, and he was transferred to the hospital at Washington in June. At this time the Romberg symptom was very marked, there was much difficulty in walking, and lightning pains and gastric crises, attended with very great prostration, were present. Tactile sensibility in the feet was much impaired and the knee jerk was absent. The paralysis of the feet grew worse in the hospital until three months after admission, when he was confined to the bed with absolute loss of power over the feet and leg muscles. He could flex and extend only the thigh and leg. The stomach symptoms were, however, much improved by this time and the shooting pains had left him. After this the improvement became more general. By the 6th of October he could slightly flex the left foot and extend the toes, and he began to go about with the help of crutches. A month later he could rise unaided from a chair. In December the knee jerk reappeared and was decided, when reinforced by clasping the hands. He walked about at will with the aid of a cane. He was allowed liberty and thereby came his downfall. He repeat-

edly returned to the hospital intoxicated and finally began to smuggle liquor in with him. His term of service in the Navy had expired, so he was discharged from the hospital.

The treatment in this case was mainly copper arsenite. It was increased rapidly and for a time he was taking gr. $\frac{1}{12}$ at a dose. Potassium iodide was given alternately with the copper in daily doses of from 40 to 80 gr. During October iodide alone was given, after which the former plan of alternations of each for a few days was again adopted. Galvanization of the spine was used, as was also strychnine, for a time; neither of these seemed to benefit him. Cholagogue laxatives were frequently given throughout the treatment.

Copper has a decided tendency to excite neuritis. It is for this reason that it is advisable to omit its use at intervals; and especially is it necessary to employ laxatives and salines. These have a much better effect than the iodide, although both were used in this case.

It appears, then, that in old cachectic cases of syphilis and in the so-called parasyphilitic forms of the disease it is of benefit to establish a tolerance for copper sulphate, and then employ it in doses of gr. $\frac{1}{10}$ daily and to add to this medicine blue mass in daily dose of gr. iss or more if it will be borne.

It is probable that most if not all of the lymphatic nodes of the body are infected in this disease, and from these there is constantly being poured into the blood the toxin which by its continuous action produces such sad results. Copper seems to be an antisyphilitic of unusual potency, and it appears to act at its best when aided by the antiplastic effect of mercury, which probably softens and renders more permeable the hardened and enlarged glands.

The treatment of acute syphilis by this method is very satisfactory. In the stage of secondary eruption $\frac{1}{80}$ of a grain cupric sulphate is given with one grain of blue mass thrice daily. An extra grain of blue mass is added after several days, and still another after a short interval. It is well to push the mercury a little in treating early syphilis. While in charge of the Naval Hospital at Washington, D. C., I treated a number of cases of syphilis in this way, and I give below a few details of the number there remaining, at the time I left the hospital:

R., a young and vigorous subject, took for seventy days $\frac{1}{80}$ gr. of copper sulphate, 5 gr. of blue mass, and a grain of dried sulphate of iron thrice daily. His symptoms promptly disappeared. The treatment was continued in order to neutralize and eliminate the poison as thoroughly as possible during the four months' time it was my custom to keep acute cases in the hospital for treatment.

P., took copper, iron, and twelve grains of blue mass daily for 62 days with only benefit.

McG., took the same treatment with 12 gr. of blue mass daily for 68 days.

K., took for about a month the copper, iron, and fifteen grains daily of blue mass. He then complained of a feeling of prostration and of a little headache. On decreasing the blue mass to twelve grains daily these symptoms disappeared and he bore his medicine well.

C., took for 54 days the copper, iron, and 12 gr. daily of blue mass.

A., for 25 days took exactly the same medication as C.

K., No. 2, took with the copper and iron, 6 gr. of the blue mass daily for 102 days.

This treatment speedily removes the secondary symptoms. It is rare for mucous patches to present themselves during this treatment. No signs of ptyalism appeared in any of these cases.

I have used copper alone in the treatment of cases of acute syphilis with very good results, and without complications. The treatment was continued for about nine months. The glandular enlargements and hardenings became softer and almost disappeared, and the general health was kept vigorous. Copper alone is, however, very slow in removing the secondary symptoms. (See MEDICAL RECORD, February 3, 1894.)

While at the Naval Hospital, Washington, and previous to using this treatment I had for many months given the copper with inunctions of the ointment of mercury. The inunctions were used with the usual precautions as to cleanliness and change of site, once daily, commencing with forty grains and increasing the quantity by ten grains a day. The quantity given in each case daily varied from 40 gr. to 180 gr. according to the powers of endurance of the patient. A peculiarly serious case came into the hospital with extensive rupia and tertiary ulcerations appearing about six months after infection. The patient did well [illegible] copper internally, combined with a minimum [illegible] of the ointment. Iodide was used also in the [illegible], and the man went back to duty after six [illegible] treatment. I did not find the inunction to [illegible] better than the internal medication [illegible] adopted. The copper, when taken with [illegible] in acute syphilis, in addition to acting as a [illegible] agent in itself decidedly increases the to[illegible] the patient for mercury.

An experience of many years has led me to [illegible] late my belief as follows:

1. The treatment of syphilis in all its [illegible] inclusive of the cachectic and the parasyphilitic forms, is well founded on sulphate of copper in average dose of $\frac{1}{80}$ gr., aided by such a quantity of blue mass as is borne readily by the patient.

2. In old syphilis in any form the copper should be given in minute doses, and gradually increased as tolerance is established, until the usual dose of $\frac{1}{80}$ gr. is given, when the mercurial should be added in a rather small dose. It is sometimes better to give the medicine only on alternate days.

3. In acute syphilis the copper salt is to be given in the dose of $\frac{1}{80}$ gr. and the mercurial added at once and increased as much as the patient will tolerate, in order that the disease shall be neutralized and eliminated as completely as possible.

4. Iodine, iron, arsenic, and tonics of any sort while useful, occupy a subordinate place in the treatment of syphilis.

5. Alcohol, and especially tobacco, should be forbidden to syphilitics.

NAVY YARD, NEW YORK.

**Herpes Zoster Followed by Motor Troubles.**—Vilh. Magnus reports three cases, the first of a man of fifty-five years who had an attack of herpes zoster affecting the ulnar border and the internal surface of the left forearm, extending to the internal and external surfaces of the arm. There was violent pain and increasing paresis of the limb, which became finally almost paralyzed. It is probable that the sixth and seventh cervical ganglia were affected, and that the virus (microbe or toxin?) traveled through the blood vessels to the first gray cornua, inducing a condition resembling polyomyelitis. Great improvement followed hospital treatment. A second case was a man of seventy years, who had paralysis of the right arm after herpes zoster, and completely recovered. The third patient was sixty years old, and after herpes of the right side suffered from paresis of the arm and hand.—*Norsk Magazin for Laegevidenskaben.*

## ANEURYSM OF THE TRANSVERSE ARCH, WITH OBLITERATION OF THE INNOMINATE AND LEFT COMMON CAROTID ARTERIES.

By U. S. BIRD, M.D.,
TAMPA, FLA.

The facts in the following history and the developments of the autopsy seem to be sufficiently interesting to be recorded. It is to be regretted that a more careful dissection was not made, as some points in collateral circulation, a most interesting detail in this case, might have been studied.

I first saw the patient June 27, 1903. The clinical history was as follows: L. W., colored, age twenty-seven years, born in Alabama. Faints occasionally. Mother had same trouble. Four years ago she suffered from temporary blindness, and about this time was afflicted with right hemi-

plegia. About three months since, March 20–30, 1903, she noticed a swelling in her neck about one inch in diameter, in the interclavicular notch. Has little appetite, but swallows easily; lies down with difficulty; has a "cold;" no bowel movement in ten days.

Physical examination showed a colored woman, average size, emaciated, and apparently suffering greatly. She was hoarse and breathed with difficulty. Any exertion, as talking or moving, increased her suffering. For this reason few questions were asked. Both radial pulses were about 120, barely felt. The neck and chest presented the appearance seen in the illustration. The largest dimension of the tumor was 6½ inches; across the upper part 3 inches; lower part, 4 inches; elevation above surface of chest, 1½ inches; extension up the neck above right clavicle, 1¾ inches. She complained of a burning sensation, but no pain in the tumor. Palpation caused much pain, so little was done. The tumor pulsated strongly, both to sight and touch. The photograph was taken on June 28, and she died of laryngeal paralysis June 29, at 3 A.M. I made the post-mortem examination that morning. There was much difficulty in removing the sack, which was about ¼-inch thick, dense, and strongly adherent to adjacent structures. It was also nearly full of laminated, more or less organized clots. The upper part of the sternum, and the sternal ends of both clavicles, and both first ribs were included in the sack, such included portions being mostly destroyed. Because of adhesions the sack was torn. It, with the arch of the aorta, was removed, containing the included bones which were integral parts of the sack, as their removal would have destroyed its shape. After the blood and loose clots were washed out it measured 2x4x5 inches, and weighed one pound.

It was interesting because of the extent of its development and the rapidity of its visible growth. But by far the most important facts were discovered during the examination of the transverse arch, from which the tumor sprang, and its branches. The condition found was most remarkable, and no account of anything approaching it has come to my notice. The sack was situated above and in front of the aorta, communicating with it by an opening which extended along the length of the transverse arch, about 1½ inches. The inferior wall of the artery was split, and the inner surface examined for the openings of the branches. Only one opening was seen, which a probe identified as the left subclavian. The other branches were discovered on the posterior wall of the sack. The left common carotid was contracted and filled with a dense, organized clot. This was pulled out with difficulty, and the vessel dissected to its ending in a pouch, after a short turn to the right, in the fibrous tissue of the sack. The right common carotid and subclavian were large and easily found. Below their origin was the remains of the innominate, which, a short distance below its division, contracted and ended in a blind pouch. The above facts were determined only after a most careful examination and dissection, eliminating every source of error. No anomaly was found in the origin nor distribution of the vessels, although a possible anomaly was carefully searched for because of the unusual conditions obtaining. The conclusion from the evidence is that, with the innominate and left common carotid arteries obliterated, the circulation of the upper part of the body was provided for by the development of an extensive collateral circulation. The trunk may be easily disposed of, as the ligation of the innominate seems to have been followed by no circulatory trouble. But the circulation of the head must have depended on the intercostals, and the internal mammary and axillary branches. Thus, the arterial current, in order to reach the right side of the neck must have traversed a complete additional circle. Such a condition not being suspected it was not investigated.

An anatomical preparation of the specimen would have been interesting and valuable. As it is, it must remain a unique instance of nature's resources in this direction. It is safe to say that no surgeon will attempt to induce a similar condition in the human subject.

---

**Piano Playing and Neuroses.**—Halle of Berlin states that out of every one thousand young girls who begin to learn the piano before they are fourteen, six hundred are affected by some kind of nervous disease, while out of one thousand other girls who are not taught the piano only one hundred suffer in a like manner. The doctor recommends that the study of the piano should not begin until after the age of sixteen.

## A CASE OF COMBINED PYLORIC CANCER AND PHLEGMONOUS GASTRITIS.*

By G. W. McCASKEY, A.M., M.D.,
FORT WAYNE, IND.
PROFESSOR OF CLINICAL MEDICINE, FORT WAYNE COLLEGE OF MEDICINE.

SUPPURATION as a surface process in gastric cancer is probably not very rare, but its occurrence with the formation of a distinct and well-defined abscess cavity in the stomach wall is certainly a pathological phenomenon of interest.

The patient, Mrs. T., aged twenty-nine, was seen in consultation with Dr. L. P. Drayer, on February 18, 1903. She had passed through a normal confinement three months prior to my visit and gave the following history: She began to have stomach distress, which came without relation to meals, two months before her confinement—that is, five months prior to my visit. The stomach pain came in spells lasting for an hour or two. Two weeks before her confinement she began vomiting, the symptom being attributed, and of course very plausibly, to the nervous and vascular disturbance attending the latter period of pregnancy. The vomiting occurred regularly with relation to ingesta of any kind, everything being partially or wholly rejected very soon after being swallowed.

The physical examination was negative, excepting a vague and ill-defined resistance to the left of the median line about three inches above the umbilicus, which apparently moved with the diaphragm.. This was shown at the autopsy to be a small pyloric tumor displaced to the left. Analysis of urine was negative. An Ewald test-breakfast, consisting of 300 c.c. of water and an ounce of bread, was given, and an hour later 400 c.c. of fluid was removed. The patient's stomach had been cleansed and apparently emptied by lavage three or four hours previously. Chemical analysis showed the absence of free HCl, presence of lactic acid, complete starch transformation with a very faint biuret reaction. The fasting stomach always contained a quantity of fluid in which a few pus cells could be found, but occasionally there was considerable pus mingled with the fluid. There was stomach epithelium in abundance, but no tissue fragments or Oppler-Boas bacilli. Cultures from the contents of the abscess cavity, made by my assistant, Dr. Rhamy, showed the infection to be a staphylococcus.

The blood examination gave 24,000 leucocytes and 7,000,000 red cells; the hæmoglobin was not estimated.

I made at first an alterative diagnosis of cancer or phlegmonous gastritis, but upon further study of the conditions told Dr. Drayer before the autopsy that the only diagnosis that would satisfy all the requirements was both cancer and phlegmonous gastritis, and this was precisely what the autopsy revealed. The patient died of exhaustion about three weeks after my first visit.

Autopsy: The liver was small, probably weighing a little over two pounds, and apparently normal in structure. The gall-bladder was somewhat distended. Pancreas normal, except a small nodule, which was not removed. The stomach was small and around the pylorus was thickened and covered with small nodules. The mucosa showed the evidence of severe inflammation with extensive ecchymoses. In the thickened cancerous structure of the pylorus there was found an abscess cavity about half an inch from the pyloric ring. This was about one and one-half inches in diameter, and occupied almost the entire lumen of the narrowed pyloric extremity. On one side of the abscess cavity there was a small channel about the size of a lead pencil, through which so much of the stomach contents as found their way to the intestine passed.

The absence of gastrectasia is explained by the persistence with which the stomach rejected all contents.

Had the significance of the symptoms not been so completely obscured by the associated pregnancy, the case would have been a favorable one for exploration and partial gastrectomy if the more than doubtful consent for the procedure could have been obtained.

*Read before the Allen County Medical Society.

## CONGENITAL ABSENCE OF RECTUM WITH IMPERFORATE ANUS.

By G. W. SQUIRES, M.D.,
EAST AVON, N. Y.

MRS. W., aged twenty-eight, German, mother of two children, came to labor with a third child. There being a slight deformity of the pelvis, the labor proved tedious, with face presentation and unduly tough membranes. While waiting for labor to move on, I learned that the former confinements had been slow and exhaustive, the first baby coming breech first with instrumental delivery of after-coming head. There had been trouble with the after-birth and much bleeding, the child living only a few hours malformed by a spina bifida and large, watery head. The second child was still-born at seven months' gestation, having supernumerary toes and fingers with harelip. After twenty-four hours' labor with only manual assistance, the third child was delivered, to all appearances, a well-formed, vigorous boy, the parents pleased with a howling youngster, who had all the symptoms of entering on life in earnest. I made one call early next morning, finding mother all right, and an experienced nurse pronouncing baby in the best condition. In four days I was sent for to see the baby, who had been in pain for two days, nothing having passed the bowels. The nurse became anxious when she noticed the baby straining and constantly trying to move the bowels; the kidneys had acted freely. I found the abdomen very much distended, gas could be heard moving around in the bowels. There had been no vomiting, but the child, after the second day, refused the breast. On further examination I discovered complete absence of anus and no sign of even an effort of nature to locate an anus in the buttock. Palpation failed to detect the presence of a distended rectum. Cœliotomy was immediately done. The left side was opened, and without much trouble the colon was drawn up and out, sewed to abdominal walls, and opened, when a quantity of meconium and intestinal contents escaped, to the great relief of the baby, which, in a short time was sleeping. In two hours it returned to the breast with a relish. On the second day jaundice began to make an appearance, and the belly became distended in spite of the fact that the artificial anus was patulous, allowing free evacuation of bowels. Peritonitis had set in, and the baby died on the fifth day following operation. Autopsy revealed entire absence of rectum, the descending colon ending in a cul-de-sac at the sigmoid flexure. There was also an absence of a sphincter ani so far as could be determined, nature apparently having forgotten to complete her handiwork in the distal end of the alimentary canal.

**Homœopathy Barred from a German University.**—The homœopathic practitioners of Germany recently presented a petition to the government asking that a chair of homœopathic therapeutics be established at the University of Tübingen. It was thought at first that the petition would be granted, but a strong opposition to the measure arose, and the government finally refused to sanction the foundation of the chair.

## NEW PRESENTATION OF THE TUBERCULOSIS PROBLEM.

A NOTEWORTHY address was delivered by Prof. v. Behring before the annual Congress of German Naturalists and Physicians, held recently at Cassel. It is noteworthy in several respects—in the extreme views therein expressed regarding the universality of tuberculosis, in the direct challenge of the theory adopted by Koch of the non-identity of bovine and human tuberculosis, and in the promise held out of a prophylactic serum.

In this paper, published in the *Deutsche medicinische Wochenschrift* of September 24, 1903, the writer quotes the saying of, we believe, Esmarch that "we are all a bit tuberculous," and adduces statistics from various sources to prove that this is not a mere phrase but is the expression of an actual fact. It is asserted that the tuberculin test proves that from 90 to 95 per cent. of the community is infected with tuberculosis. If this is true, and v. Behring believes it is, of what advantage, he asks, is isolation in preventing the spread of the disease? It is surely not practicable to isolate 95 per cent. of those in active life, or to place them under treatment in sanatoria in order to preserve the remaining 5 per cent. from the danger of infection. But this would not be necessary, even if it were practicable, for a sharp distinction must be made between tuberculosis and pulmonary consumption, the presence of the former being practically a negligible quantity, except in so far as it creates a predisposition to consumption.

But how comes it that this enormous percentage of living men harbors the tubercle bacillus? Whence comes the infection? The writer of the paper does not accept the growing belief in the contagiousness of consumption, as generally understood. He thinks that tuberculosis is seldom acquired by adults, the seeming instances of such acquisition being merely the lighting up of a slumbering focus of infection which the individual has carried from infancy, the outbreak being caused by any of the recognized factors—exposure, mental strain, starvation, overwork, etc., which depress the vital powers and weaken the normal resistance of the organism. He also dismisses the now little credited theory of hereditary transmission of the disease. But if tuberculosis cannot be, or at least very seldom is, acquired in adult life, and if it is not congenital, when and how does infection occur? Here Behring joins issue squarely with Koch, for he asserts, and devotes a large part of his essay to prove, that the main, though not the only, source of infection in human beings is the milk, whether it be the milk of the tuberculous mother or that of a tuberculous cow. We cannot follow him here in the argument by which he seeks to prove the truth of this assertion, but will note only the distinction which he makes between infants and adults in their liability to infection through the digestive tract. In the young of man and many other animals the intestinal epithelium is so constituted as to permit the entrance into the blood stream of bodies which the adult mucous membrane excludes. The pores of the intestinal filter in infants are large and readily permit the passage of various microorganisms, tubercle bacilli among the rest, whereas in the adult they are much finer. In the new-born, for example, Römer has shown that albuminous bodies can enter the blood unchanged, whereas in adults they must be split up by digestion into peptones before they can pass through the dialyzing membrane which in the developed individual constitutes the lining of the intestinal canal. Adults can usually drink with impunity the milk of tuberculous cows, infection through this means occurring only when there is some lesion of the intestinal mucous membrane breaking down the normal defences.

Behring does not, however, contend that the infection of infants can occur only through milk, for the specific bacilli may reach the intestinal canal in other media. When a young child is kept in the same house or the same room with a patient in the active stage of pulmonary tuberculosis, the bacilli contained in the spray sent out in the act of coughing or set free in dust contaminated with dried sputum may lodge in the mouth or nasal cavities of the infant and thence readily gain access to the intestine. Even older persons may become infected in the same way, but only when some previous disease, measles for example, has worked changes in the mucous membrane of the digestive tract whereby the barrier to the passage of formed bodies which the normal intestinal mucous membrane offers has been weakened.

The most interesting, and at the same time the most vague portion of v. Behring's address is that in which he speaks of his work looking to the elaboration of an effective prophylactic. This consists not in the administration of an antitoxin derived from without, but in an isopathic immunity established within the organism by the self-elaboration of protective bodies—in other words, by a process of vaccination or "jennerization." The method has as yet been employed only in animals, and the author acknowledges that he is not ready to put it to the test in human infants. It is one thing to employ a method which saves from tuberculosis 499 calves but may kill the five-hundredth, and quite another to expose one out of five hundred human beings to the same danger. A farmer will willingly risk the sacrifice of one calf in order to save from disease the rest of the herd, but when the question has to do with human babies it presents an entirely different complexion. However, the matter is not concluded, indeed is hardly begun, and v. Behring is evidently convinced that there is a solution of the problem, and that he will yet be able to announce the discovery of a vaccine against tuberculosis. One way in which the desired result can be milk"—that is to say, of the milk of cows which have obtained may possibly be in the use of "immune

been immunized against tuberculosis. The immunity so produced is as yet only temporary, but some means may be discovered of increasing its period of effectiveness. But even if the immunity so produced is but temporary, provided it is real, the continued use of "immune milk" might well preserve the baby until such time as, in the course of normal development the pores in the intestinal sieve are closed and the mucous membrane becomes impervious to microorganisms. To forestall the demands upon him which he anticipates the publication of this paper will bring, the writer announces that he will not answer any letters asking for samples of the immunizing material which he feeds to calves, and which he emphatically says should on no account be be used in the attempt to effect immunity in the human infant. When his investigations are concluded and when he has succeeded—and he seems confident of success—in the discovery of a method of protecting man against tuberculosis as surely as Jenner's discovery protects him against smallpox, then the world will be apprised of the fact—and we may add the "Fabriken" will all be working overtime. When the discovery is announced and its efficacy demonstrated we shall welcome it, but in the meantime we should not advise the razing of all sanatoria or even a pause in the building of new ones. We fear they will be needed for many weary years to come.

## THE MEANING OF URIC ACID AND THE URATES.

A PAPER with this title, first read before the Washington State Medical Society, Tacoma, in June, 1902, and afterward published by the London *Lancet*, has aroused much attention both in Great Britain and in this country. The author, Dr. Woods Hutchinson, Professor of Comparative Pathology, University of Buffalo, expresses his original views with lucidity and conciseness. The etiology of gout has long been a stumbling-block to medical men, and although there has been no lack of theories propounded as to the exact nature of the disturbance in metabolism distinctive of the disease, no conclusive decision has yet been come to. The greater number of those who have made a special study of the matter have held that in the condition known as lithæmia there is a deficiency of proper oxidation of food, and that the elimination of the waste products of the body is imperfect. All have agreed that the urates play an important part in the pathology of the malady, although authorities differed with regard to the precise position these bodies fill.

Dr. Hutchinson points out that the drift of opinion is at the present time clearly tending to the conclusion that uric acid is in no sense longer to be regarded as a product of the imperfect combustion of proteids into urea, that no mere excess of nitrogenous foods as such is capable of producing it, but it closely depends upon the amount of nucleins, purins, and the alloxur group in the food. The uric acid produced in health comes from but two sources—about half our normal output is due to the exogenous uric acid of Chittenden—and the remaining amount of uric acid produced, the endogenous moiety, from the destructive metabolism of the nucleins of the body tissues.

The article by Dr. Hutchinson is a long one, and the argument in support of his theory is marked by close reasoning and clear explanations, and throws much light upon the meaning of uric acid and the urates. One portion of the paper is so neatly put that it is worth quoting at length. It is as follows: "Is uric acid, with its congeners or precedents, the cause of gout and the lithæmic state or merely a symptom? On the one hand, we find the bulk of English and American observers, and on the other hand the mass of the continental, headed by Levison and Ebstein. On the face of it the former theory appears far the more probable, for we have apparently naked-eyed proof of its correctness, in the form of visible deposits of the urates of sodium, forming the tophi and acting as apparent irritants in the inflamed joints; while the acute attack is usually accompanied by a great increase in the excretion of urates and its decline by a corresponding diminution. Garrod and many observers declare that the amount of uric acid in the blood itself of gouty patients is markedly increased, while Haig furnishes us with a graphic picture of solid crystals of uric acid, crystallizing out of the blood stream in the sheaths of the nerves, in the parenchyma of the kidney, in the mucous membrane of the nose and throat, the tissue of the nostrils, and every other region which furnishes the ache in gout, giving rise to chronic neuralgia, nephritis, rhinitis, and tonsillitis of gouty subjects. But the value of this evidence has been greatly undermined of late years. In the first place, very serious doubt has been thrown upon the power of uric acid as such, or even of the urates, to give rise to serious irritation in the tissues. It is alleged to be almost absolutely non-irritating, as much so as its relative urea, in support of which might be advanced the fact of its occurrence in large amounts in some of the leukæmic conditions without giving rise to any irritation whatever. The same is true in children, in whom it will be present in perfect showers in the urine without giving rise to any symptoms except the renal or vesical irritation due to its mechanical effects. It has also been injected in large amounts into the body of animals as well as administered in their food, with no toxic results whatever or more than purely local irritation."

Medicinal treatment throws little light on the cause of gout—nothing certainly in favor of the uric-acid theory. The remedies used have been almost as the sands of the seashore in number. The useful drugs appear to be those that either reduce the putrefaction in the alimentary canal by inducing purgation, or need so great a quantity of water for their solution, that they literally wash out the tissues.

Dr. Hutchinson considers tophi and their congeners in gout as purely symptomatic in their character, but gives only a suggestive outline of the reasons which have led him to this opinion. His conclusions are as follows: (1) There is no connection whatever between the production of urea and of uric acid, hence interdiction and marked limitation of animal or of nitrogenous foods, as such, in gout is irrational. (2) The uric acid produced in health comes exclusively from two sources, the larger moiety, or exogenous uric acid of Chittenden, from the nucleins and purin bases of the food, the

House Commissioner, that instead of the block proposed the board take the adjoining block to the south, which is known in the district and in the Health Department records as the "lung" block, because of the prevalence of consumption there. Many of the houses in the block, Mr. De Forest says, are permanently infected with the germs of tuberculosis. Certain of these houses, namely, those at 140, 142, and 144 Cherry street, have had, in the past five years, as many as twenty-two cases of pulmonary tuberculosis in each house as far as the records of the Board of Health go. It is probable that the actual number of cases of tuberculosis in each house is double this amount, as it is well known that not more than one-half the cases are reported to the Board of Health. This suggestion to raze the "lung" block will be considered at the same time as the original proposition for a park.

**Results of the New Food Inspection Law.**—Dr. Harvey W. Wiley, chief of the bureau of chemistry, of the Department of Agriculture, reports that as a result of the inspection of imported foods by his bureau under the new law authorizing the exclusion of impure or misbranded foods, twenty samples, or about 10 per cent., of 205 invoices examined, had been condemned and rejected. Of these twenty samples five were of Rhine wine, and contained salicylic acid; two of white wine, Sauterne, and contained sulphurous acid; four of olive oil, containing cottonseed oil, and misbranded; three of frankfurter sausage, containing harmful preservatives; four of vegetables in cans with lead tops touching the food; one of vinegar, misbranded and made from distilled alcohol, and one of coloring matter for foods, in which coal-tar dyes were used.

**An International Congress of Ophthalmology** will be held at Lucerne, Switzerland, in September, 1904. An innovation in the conduct of the congress will be made in order to promote discussion. It is announced that all papers, to be presented to the congress, must be sent to the secretary not later than May 1, 1904. These will be printed and a copy of each paper will be sent to every registered member some weeks before the opening of the congress. These papers will then not be read, but members are urged to be ready to discuss them when their titles are announced.

**Licensed Osteopaths in Missouri.**—The new Missouri State Board of Osteopathy, which was created by the State Legislature at its last session, has licensed 153 persons, including some thirty women, to practise this method.

**Appeal for the Red Cross in Turkey.**—A petition, signed by twenty-one men and women, constituting the American Missions at Monastir, Philippopolis, Salonika, and Samakoff, was recently presented to United States Minister Leishman and to the British Ambassador, Sir Nicholas O'Conor, requesting them to secure the admission of a corps of the Red Cross Society into Turkey; or, as an alternative, permission for the members of the American Missions to dispense charity. The petitioners assert that thousands of the inhabitants of the disturbed districts are houseless and are already reduced to living on roots and grasses. In many places the wounded are lying without medical attendance, and with no remedies or palliatives within reach of their friends, and whole districts are weltering in blood, without a single doctor or trained nurse to relieve the suffering. Should the authorities object to the entrance of the Red Cross Societies, but consent to allow the private distribution of relief, the mission would be willing to undertake it to the extent of limited ability, should funds be sent for that purpose. "In any case," the petition concludes, "the call is for urgent action, and it should be prompt if it is to be effective. The gangrene in the wounds of men and women will not stay its action to await prolonged formalities, and starving babies will wail out their lives if succor is delayed. Needless, however, to multiply words, since our appeal is to men whose sympathies are keen and who represent nations always quick to respond to the cry of help from those in need and in misery."

**Typhoid Fever in Algiers.**—A serious epidemic of typhoid fever is reported to be prevailing among the troops in Algeria, and the military manœuvres which were in progress have been suspended.

**New Quarters for the House Staff at Roosevelt.**—A "staff room" for the internes is to be added to Roosevelt Hospital. It is to be a one-story structure of ornamental brick and plastic slate, and will be on Fifty-ninth street, just off the main hospital building. It is to cost $4,500. The plans have been filed with the Building Superintendent.

**Consolidation of Medical Schools in Washington.**—The medical and dental departments of the National University and Columbian University at Washington have consolidated, and at the beginning of the fall term the former medical and the dental students of the National University will matriculate as Columbian students. Drs. Baker, J. Hall Lewis, and E. A. de Schweinitz, representatives of the two universities, have had the question of the merger of the medical and dental departments under consideration for some time, and the arrangements have recently been completed.

**Obituary Notes.**—Dr. GEORGE W. BOWEN died in Philadelphia on October 1 at the age of fifty-six years. He was graduated from the Medical Department of the University of Pennsylvania in 1872.

---

**Sarcoma of the Femur Recurring after Amputation and Cured by Injections of Coley's Fluid.**—H. B. Sweetser states that sarcoma of the femur treated by operation is almost sure to recur. This appears to be true whether resected or amputated in continuity or disarticulated at the hip joint. The type of tumor does not seem to make much difference. Almost the only cases that have not recurred, or if recurring have disappeared again, are those which have freely suppurated after operation or which were inoculated with erysipelas poison, or which were subjected to injection with the toxins of streptococcus erysipelatis and bacillus prodigiosus, the co-called Coley's fluid. In the pre-aseptic days, when operative wounds almost invariably suppurated the results were better than they are now. The patient whose case is here reported was a man thirty-three years of age. Sarcoma of the right knee developed, following injury. The tumor was opened, the patient objecting to amputation without positive proof of malignancy. Microscopical examination showed it to be a large, spindle-celled sarcoma. Later the thigh was amputated. About five weeks later recurrence was noted. Injections of Coley's fluid were begun. They were always given in the neighborhood of the tumor. They were very painful and raised a lump which did not disappear for a number of days. The injections very promptly controlled the pain, which was intense. There was very little change in the appearance of the leg or tumor until at least fifteen injections were given Then suddenly a very rapid retrogression took place. The temperature and pulse responded almost as promptly as did the pain. The patient now weighs 180 pounds, having regained all he lost during his illness. He wears an artificial leg, works daily and feels in perfect health.—*Northwestern Lancet.*

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

FEVER AND DYSENTERY IN SOUTH-AFRICAN WAR—BRITISH ASSOCIATION—DR. TOLMAN'S LECTURE—EDIBLE FUNGI—PREVENTION OF TROPICAL DISEASES—THE OUTBREAK ON THE TRAINING SHIP—CANCER FUND—REVACCINATION—KING'S SANATORIUM—MORTALITY OF THE MONTH.

LONDON, September 18, 1903.

THE report of the commission on dysentery and enteric fever in the South-African War has just appeared. The introduction is dated November 29, 1901. Why this delay in producing it? It cannot be that the printing, though plates and maps illustrate the report, has taken nearly two years. Perhaps the differences of opinion expressed have had some influence, for they are quite irreconcilable, and will certainly be quoted as one more example of how doctors disagree. The commissioners were Lieutenant-Colonel Bruce, Col. Lane Notter, and Dr. W. J. Simpson, and each of these expresses his own opinions. Colonel Bruce made a bacteriological examination of eighteen cases of dysentery and seven of enteric fever. His report on the conditions is not controverted. He concludes that dysentery in South Africa is not caused by amœbæ, the organs are sterile, the causal agent being confined to the intestines. No microorganism stands out prominently in the large intestine, as in cholera.

There is not sufficient evidence that bacillus coli take on pathogenic qualities. There is no connection between dysentery and enteric, Eberth's bacillus not being found in dysentery. There is some evidence that dysentery following enteric may be really relapse of the enteric when the large intestine has been attacked.

Professor Simpson's report follows and deals with many points. He finds enteric fever a common scourge in the civil population of South Africa, and dysentery virulent in the mines. He attributes them mainly to insufficient protection of the water supplies and neglect of proper disposal of excreta and slop water. In the army the above causes were sure to prove serious, and in the first year of the campaign the deaths from enteric fever were more than six and one-half times as many as those from dysentery, and in the second year nearly six times. Drinking surface water was the commonest cause of dysentery, but sand lodging on the food during dust storms was also a cause. It is suggested that meat should be sent in tins containing only a single soldier's rations. He would thus be able to protect himself from dust and flies on his food. Wells were dug at the Modder river, and the requisite number available two days before the troops began to leave. At Paardeberg this was not done, though Dr. Simpson shows that the geological formation was well adapted for this natural precaution. These two facts are examples of what is evident throughout the report—that the catastrophes of the campaign were due to the want of forethought and unpreparedness, which was the bane in every department of the army. In many respects the neglect seems criminal. The authorities had been warned over and over again that a breakdown was inevitable unless certain provisions were made. But they sent out their armies unprepared for war, and the medical department more than half below its proper number, and then inadequately equipped. Dr. Simpson gives a summary of the sanitary state of some camps, which is not quite new, as the facts were obvious to many and have been discussed in the press. But on many points the statements of the reporters are contradictory. Here is a striking example: Dr. Simpson says it was "the general exception for the water to be filtered or boiled," but Colonel Notter declares this statement to be "far from the real facts," and that in his "experience it was rather the exception to find water not boiled or filtered." He further impugns Dr. Simpson's description of the general state of the camps as "grossly exaggerated." There are other strange contradictions in this report which may possibly serve the military autorities as an excuse for further delay in commencing reforms. Parliament is not sitting, and a cabinet crisis is to-day sprung upon us. Is it likely anything will be done? Yet grave responsibility will be incurred by further neglect. The least to be done should be to appoint one or two experts to examine and report on the divergent views of the commissioners and make some recommendations.

The meeting of the British Association is among the things of the past. It is said to have been successful, but it has not excited, I think, as much interest as usual, although it has ventured to discuss subjects out of its usual range, or, at least, on the borders. Some of the speakers and even readers of papers, have attempted to apply science to political questions, and in doing so have exhibited themselves more as politicians than scientists. This was especially noticeable, according to the reports of the proceedings in the Section of Economical Science, in which the burning question of the day was introduced in three papers. The first of these was entitled "Statistical Methods and the Fiscal Controversy," by Mr. Bowley, and was a criticism and a warning with reference to the confusion due to erroneous uses of statistics in argument. He was followed by Rev. Dr. Cunningham, who promised to treat the question as entirely an economic one, but appeared to some to deviate from this intention, for he put forward the paradox that retaliatory duties could be supported on free-trade principles. A subsequent speaker said this showed him to have a "double personality," and another said he was a competent economic historian, but not a politician. The third paper had opened the floodgates by references to "absurd proposals," the "folly of lunatics," and other choice phrases which hardly accord with the notion of scientific discussion and led to statements and expressions not often heard in the proceedings of professed economists. However, they produced laughter, not to say jeers, on both sides, and the usual notes of assent and dissent.

I must turn to a subject more allied to medical studies. A report was presented by a committee on the conditions of health in schools. Sub-committees had collected information on the general problem of school hygiene. Special attention had been directed to the causes of defective eyesight in school children and the conditions necessary to preserve the sight from injury in school life. One of these was said to be the bad print of school books, and it was actually suggested that these books should be "passed" by some recognized authority on hygiene before being admitted for use in schools. The committee pointed out that the two sexes being about equally occupied in school, the inspectors ought to be men and women in equal numbers. The committee proposed to memorialize the Education Department. (1) To adopt or recognize some more thorough and practical test of a teacher's knowledge and experience of the application of health conditions in school life. (2) To protect health in school life by making practical knowledge of hygiene as applied to school life an essential qualification for those to whom it entrusts its school inspection. It would seem that a more ready means of attaining the object, and more likely to be successful, would be to appoint a few medical inspectors.

Another hygienic discussion was on garden cities. You have heard of the project for establishing them put forward in Mr. Ebenezer Howard's book on the subject as a solution of the problems of overgrowth in great cities and depopulation of rural districts. A bold experiment is to be made in this direction. Mr. Howard, who was present at the discussion, stated at its close that a site of 3,800 acres of land had been secured for the purpose, and that the Great Northern Railway Company had begun the erection of a station on the estate.

It is announced this morning that the Limited Company for carrying out the first city is successful, the applications for shares being sufficient to justify going to allotment.

"Physical Degeneration" was the subject of another paper which did not support the alarming assumption of some writers that one-third of our population is too poor to maintain itself in physical efficiency. This assumption is a hasty inference from the figures of Mr. Booth and Mr. Rowntree, whose laborious researches are well known and have aroused intense interest. But their investigations by no means supports this inference. In my letter of August 28 I wrote something on the subject in reference to the Scottish Commission, and may now add that this last paper supports what I then said. Doubtless many children are in want of better care and better food, but a large proportion of them suffer—not from the poverty so much as the neglect and ignorance of their parents and the waste of wages in beer, etc.

In connection with this subject, I may report that Dr. Tolman of the New York Institute of Social Service has been giving a lecture here on "Improved Conditions of Life," in which he stated the results of investigations in various countries. He said that in America industrial betterment had been carried out in many large cities, and the question as to whether it was profitable was not considered, the object of the great factory owners being rather to provide "a little heaven here below" for their workpeople.

Among the concluding resolutions of the association it was agreed to request the council to urge on the government the desirability of increased national support for the universities. The resolution hardly comes up to the president's suggestion, but to ask for £24,000,000 would be like crying for the moon.

Do you like mushrooms? Dr. M. C. Cooke has been turing on edible fungi at the Horticultural Society. e told a crowded audience that there was no royal road a knowledge of them which would enable them readily distinguish the edible from the poisonous varieties. e said he had eaten, or at least tasted, about eighty nds, but claimed no merit for venturing to do so, as he d generally obtained information which justified him. e described the principal characteristics of some twenty ible varieties found in this country, and said he could stance five times that number. He urged the necessity cooking and eating fungi as soon as possible after thering them, as in some, chemical changes set in once and give rise to poisonous substances. The ture was illustrated with numerous colored drawings, ich probably will be reproduced in the society's journal.

Professor Boyce of the Liverpool School of Tropical edicine, in a recent lecture, took a cheerful view of ogress in stamping out diseases as knowledge advanced. e can now control malaria, but must employ the est scientific methods. The awful mortality in India hardly realized by the public. In the present year, to the end of August, nearly 600,000 perished from gue. Cholera and malaria would count three times many victims. The tsetse fly had lately paralyzed de in Mauritius. The common house fly was a dan- ous and dirty insect, which should be chased from ry house. The campaign against the mosquito successful wherever vigorously fought. But England st rise to her responsibility and make much greater orts. The scientific laboratories of the country are dequate.

Dr. Williams, M.O.H. for the Port of London, reports that e outbreak of typhoid fever among the boys on board e training ship *Cornwall*, caused by the use of infected nkets from South Africa, has now terminated. From ril 8 to August 17 the cases numbered sixteen. You ll remember that it was the port sanitary officers who ced the outbreak to the infected blankets and caused e seizures of all these articles in the docks and wherever y could be traced, thus, doubtless, preventing a wide- read epidemic; for at one dock sixty-two bales were ized.

Sir Lambert Ormsby, president of the Royal College of Surgeons in Ireland, has made a vigorous appeal in the press on behalf of the Cancer Research Fund. He professes himself unable to understand why the public are so apathetic, and says while medical men are devoting their lives to this work, "those who are rich and live at ease ought to question themselves whether they are not incurring a very grave responsibility in withholding the only help they can give—money help—to this grand crusade against one of the direst foes of humanity."

Mrs. Garrett Anderson, M.D., also appears in the newspapers on another subject—vaccination. She instances, as a lesson, the Battersea epidemic, in which 220 cases of smallpox and twenty-nine deaths occurred, and says the estimated cost to the ratepayers was over £71 for every case. She adds that if the ratepayers desire to prevent the recurrence of this waste they have two potent weapons at hand: to let candidates at the election know that they demand revaccination at school age, and in the meantime insist upon every person in their own employ being able to prove having been efficiently revaccinated.

The work of building the Kings Sanatorium has begun, many men being engaged on the foundations.

The London death rate rose last week to 15.2. It had been 14.4, 14.3, and 14.1 in the preceding three weeks, but it is still below the average for the corresponding period of the decade. The same is the case in the seventy-six large towns, the rates of which, for the same weeks, were 15.7, 16.0, 15.7, and 15.8.

## OUR PARIS LETTER.

(From our Special Correspondent.)

URETERAL CATHETERIZATION MISLEADING IN SOME CASES —TUFFIER'S OPINION ON OBSTRUCTION OF THE CHOLEDOCHUS—REMARKABLE CASE OF GASTROTOMY—CHANTEMESSE'S NEW TREATMENT OF TYPHOID PHLEBITIS—SYPHILIS INOCULATED IN AN APE—TWO CASES OF TABES CURED BY MERCURIAL TREATMENT—THE MILK QUESTION—EXPERIMENTS OF NICOLLE AND PETIT.

PARIS, September 18, 1903.

DR. BAZY, surgeon at the Beaujour Hospital, and one of the best known genito-urinary specialists in Paris, does not consider a radical operation always timely in renal tuberculosis. At a recent meeting of the Society of Surgery he gave the history of a case, which justifies his opinion. Two and a half years ago he was consulted by a patient who had already seen one of his colleagues who, after having performed ureteral catheterization, found bacilli in the urine coming from the left kidney, and recommended nephrectomy. Dr. Bazy considered it inexpedient to operate, as there were no symptoms, such as pain or hæmaturia. On the other hand, repeated examinations of the urine did not reveal tubercle bacilli, but a pseudotuberculous bacillus, coloring in the same manner, but having no effect on the guinea-pig. The patient in question, a young man, is still apparently in good health, has no fever and no pain.

At the same meeting Dr. Tuffier gave his opinion on the important question of diagnosis and treatment of calculous obstruction of the choledochus. The diagnosis was often difficult, even during the operation. Former attacks of bilious colic were a useful sign, as also the size of the gall-bladder, the latter, however, were not to be counted on always.

Dr. Tuffier cited a case of cancer of the pancreas, in which the bladder could not increase in size, as the cystic canal and neck of the organ were included in the tumor. Dr. Tuffier preferred to push the stone into the bladder rather than perform choledochotomy, but when he performed this latter operation, he did not suture the canal, unless this could be easily done.

A most remarkable case of gastrotomy for foreign bodies of the stomach was described at a meeting of the Académie de Médecine. The patient, a youth sixteen years old, had entered the St. Joseph Hospital for Epilepsy. He had had melæna and a rather sharp pain, accompanied by crepitation in the left hypochondrium. The operation was performed in June, and the following bodies were removed through an orifice of 2 centimeters and a half: 8 teaspoons from 8 to 15 centimeters long, a three-pronged fork, a letter file 12 centimeters long, 2 sharp points, a needle 6 centimeters long, a knife-blade 5 centimeters long, a piece of comb 8 centimeters long, and a key. There were in all 25 bodies, weighing 230 grams. The stomach did not seem to have been affected, and the patient recovered completely.

Dr. Chantemesse has been trying a new method of treatment of phlebitis in typhoid fever, which consists in using as little salt as possible in the food given to the patient. He applied this treatment in six cases, and the œdema remained stationary. When the treatment was interrupted, the œdema increased.

Dr. Metchnikoff of the Pasteur Institute has at last been able to inoculate a young female chimpanzee with syphilis. The inoculation which was done on the clitoris was repeated after five days. On the twenty-sixth day there appeared an oval vesicle, followed by an indurated ulceration, covered by a gray false membrane. The inguinal glands increased in size on the same side. Fournier examined the animal and admitted that the lesion was a perfect type of syphilitic chancre. Du Castel said that it was not necessary to await the appearance of the secondary symptoms to affirm the syphilitic nature of the lesion. Metchnikoff has succeeded because he employed an animal which morphologically is closer to man than the other varieties of apes.

In the March number of the *Annals of the Brussels Central Polyclinic* Dr. Duhot published two interesting cases of tabes cured by an intense mercurial treatment. In the first observation the patient, a young man twenty-seven years old, had an extragenital chancre in September, 1900. Two months afterward a malignant pustulous eruption showed that the case of syphilis was serious. Twelve injections of salicylate of mercury were made. In February, 1901, there appeared gumma at the nape of the neck and eczema. In May the patient began to have vertigo, diplopia, and weak sight. The patient spoke with difficulty, there was weakness of the left arm, the papillary and patellar reflexes were diminished. Four injections of 10 centigrams of calomel and 3 grams of iodide of potassium removed all these symptoms. In July, September, and October nine injections were made. On the 17th of December there was emaciation, complete suppression of the pupillary reflexes as well as of the patella. The cremasterian and abdominal reflexes still existed. There was loss of sensation in the soles of the feet, and the patient could not walk straight. He could not stand with his eyes shut and had shooting pains in his legs. Twelve injections of calomel, one every week, were administered, as well as 3 grams of iodide daily. Points of fire were applied on the back twice a week, and static electrization of the trunk and lower limbs was applied each day for a quarter of an hour. This treatment was carried out for two months, when the reflexes had returned to their usual condition, with the except on of the left patella, which lagged a little. The patient could stand with his eyes shut, and walk in a straight line. The sensation in the soles of the feet had come back in great measure. The second observation was similar, the patient could now walk perfectly well, but the patellar reflex was still absent.

Dr. Vaillard and Dr. Georges, surgeons at the military hospital of the Val de Grâce, have established a formula for the use of iodine as a means of sterilizing water. The troops are furnished with compressed pellets of: (1) iodide of potassium 10 grams, iodate of sodium 1.56, methylene blue q. s. for 100 compressed pellets. (2) Tartaric acid 10 grams, sulphofuchsine q. s. for 100 compressed pellets. (3) Hyposulphite of sodium 11.6 grams, to be melted gently and made into 100 pastelles. The iodide pellets should be kept in a bottle. Instructions are given to the soldiers as to the method of using them, which is as follows: Filter water overcharged with organic matter. Put an iodide pellet and a tartaric pellet into a small amount of water, and when thoroughly dissolved pour into about 10 liters of water. After about 10 minutes dissolve one pellet of hyposulphite in a small amount of water and pour this into the water. The water becomes perfectly clear and can be drunk immediately.

The question of pure milk is being discussed again in the French newspapers, and the medical papers are taking it up. Experiments have been carried out at Rouen, by Nicolle and Petit, and it was found that with the exception of one sample all the milk analyzed contained a large number of bacteria, as many as 2,400,000 being found in one cubic centimeter. The conclusion of their experiments was that the best method was that already carried out in New York, viz., refrigeration, the microbes not multiplying at a temperature of 6 to 10° C.

## THE QUESTION OF AMALGAMATING THE TWO STATE SOCIETIES.

To the Editor of the Medical Record:

Sir: As a member of the Comitia Minora of the Medical Society of the State of New York I have voted against the proposition to call a special meeting for the transaction of executive business in connection with the coming semi-annual meeting. The reasons I have for voting in this way are these:

First: The transaction of executive business in connection with the semi-annual meetings of the State Society is contrary to the vote of the society when these meetings were authorized. It was distinctly stated then that these meetings should be for the transaction of scientific work *only*.

Second: It is not possible to say how largely attended this meeting will be, and to go into executive session and transact important business at such a time would look as if somebody wanted to "jam" something through which he feared would fail of passage if presented at the annual meeting, which would probably be more largely attended and representative in its character. I should feel that way myself, and I know others would, too.

Third: The Committee on Amalgamation has had no meeting since early in the summer and can have no report to offer. Nor could it prepare, in the short time between now and the date set for the semi-annual meeting, a well-considered and careful report. If a special business meeting is called, I know there are a number of New York men who are opposed to this effort unduly to hasten matters, who will be present and speak against it. I am not going to try to influence any one to act contrary to his or her best judgment. If those who attend are not willing to listen to, and be governed by, what seems to me to be reason, then I shall bow to the will of the majority as gracefully as possible.

It has been said it is "up to" certain men of the profession to bring about medical union in this State, but I doubt if there is a living man who can bring about a union satisfactory to all as matters stand to-day. There are too many conflicting opinions and interests. If there is such a man, it is certainly "up to him" to do it.

I am heartily in favor of union, as you know. I would even be willing to make great sacrifices to bring such a thing about. I would even vote to assume the association's debts, if we could in that way settle the question. I am not in favor, however, and never will be, of entering into and adopting the business schemes of the association; its death benefit fund; its medical defence union; its publications, and so on.

I am not in favor of their plan of organization, considering it decidedly less desirable than our own, but I would not stand out against that.

The State Society and the State Association are, as so clearly pointed out in the recent articles in the *Buffalo Medical Journal*, organizations with distinctly different purposes. One is for the protection of the community and the public health, while the other is a business organization established for the protection of the profession and for social and scientific purposes. You cannot unite these two bodies and have the united body retain the functions each exercised separately, without taking away from the society the strong argument it has always used when appearing before the Legislature in opposition to pernicious measures seriously affecting the integrity of our medical and other public health laws.

Either the association must drop its business undertakings, commendable as they may be when conducted by the association, and come up to our position, or we must adopt them and come down at once from our lofty position as a public body to that of a private corporation chartered for business and social purposes. This step is but the beginning of the end, but if the profession is willing to have it so, then so let it be. It means, however, the opening of the doors in New York to all the quacks and charlatans in christendom. The Medical Society of the State of New York will never be able after such a union to appear before the Legislature and argue successfully in favor of its exclusive right to name the members of the State Board of Medical Examiners representing the regular profession, which privilege it possesses to-day, and meet the charge that the State has no right to confer public functions on societies and organizations created for the personal benefit of individuals or bodies of individuals. That statement was made last winter by one of our State Senators when I appeared before the Legislature in behalf of trained nurses. I was able to convince the Senate Committee that the Honorable gentleman was wrong; that the State Society was a public body, created for public purposes and for nothing else.

The Medical Society of the State of New York has been able, in the years of its existence (nearly a century now) to accomplish great things for the public at large and for the medical profession. Much as I favor medical union, I feel we should move slowly in this matter, and before we agree on any plan of amalgamation its possible effect on our future usefulness should be carefully looked into.

There has been an interval of over twenty years since the rupture occurred which gave rise to the formation of the State Association. We have been getting closer together all that time, and now since the American Medical Association has made it possible for union to occur, we do not want to lose our heads and plunge into any compact which will be worse than remaining as we are. On the other hand, I do not think either party is justified in standing out for all the concessions coming from the other side.

I believe we ought to be willing to make mutual concessions, providing we are not asked to adopt such provisions, or amendments to our charter, as will entirely alter the complexion of our organization and change it from a public body, with public functions, into a private corporation organized for business and social purposes and for private gain.

Frank Van Fleet, M.D.

New York, October 5, 1903.

## Progress of Medical Science.

*The Boston Medical and Surgical Journal, October 1, 1903.*

**A Note on the Transmission of Whooping-cough by Indirect Contagion.**—John Lovett Morse, in answer to a circular letter on this subject, sent to the members of the American Pædiatric Society, received forty replies. He says that it seems hardly possible to draw any very positive conclusion from these replies, except that very little is known as to the indirect contagiousness of whooping-cough. The cases reported, although very few, seem to justify the presumption that whooping-cough may be carried by third persons or by clothing and other articles. The fact that forty men of such wide experience have seen such a small number of cases in which they could, satisfactorily, to themselves, exclude direct contagion shows, however, that it must be very seldom that whooping-cough is carried in this way.

**Urethral Tuberculosis, with Report of a Case.**—Arthur L. Chute says that relatively few cases of urethral tuberculosis are reported. This affection may be secondary to a purely genital tuberculosis or to a tuberculosis of the urinary tract. The case here reported belongs in the first class. The lesions can be grouped under three headings: Those of the mucous membrane; those of the corpus spongiosum; and those of the periurethral tissues. Two sorts of lesions of the mucous membrane are commonly seen—the granulation and the ulcer. Frequency and tenesmus are early symptoms. For the same reason hæmaturia is often seen. Incontinence has not been a very unusual symptom. The discharge is commonly scanty and whitish rather than purulent. Pain on urination is quite a constant symptom. A nodular condition of the urethra is less common than the discharge or pain. In certain cases obstruction to urination has

been a prominent symptom. The prognosis of this disease depends very largely upon the extent and importance of the primary focus. The hygienic treatment should hold the most important place. Then forced feeding, arsenic, guaiacol, creosote, together with aids to appetite and digestion, are of service. Seashore camping for patients with this disease is of the greatest advantage. There is a great question as to the utility or desirability of local treatment by applications to the urethra. When the urethra is greatly ulcerated, perineal urethrostomy will give great relief, and may bring about recovery. In some instances of very advanced disease, amputation is the best procedure. Whatever operative procedure may be indicated, the importance of keeping up hygienic treatment must not be overlooked.

*Journal of the American Medical Association, October* 3, 1903.

**Some Clinical Aspects of Tuberculous Peritonitis.**—J. Eichberg reports eight cases, and gives a general description of the disease. He does not regard laparotomy as a cure for the disease. The patient should be put on an anti-tuberculosis régime and incision used only to relieve some definite condition which calls for it.

**Essentials and Non-essentials of Ophthalmic Asepsis.**—H. Gifford calls attention to the bacterial contents of the conjunctival sac and says that it is a practical impossibility to keep them out. He therefore does not think it necessary that the eye surgeon should adopt all the precautions the general surgeon thinks necessary. A general bath for the patient is not necessary just before operation. The skin of the lid should be scrubbed with sterile swabs and a 4 per cent. silver solution painted on. The author then goes in detail into the methods he follows, his object being to simplify matters without neglecting any needful precaution.

**Tuberculosis in the Negro.**—S. Hanis discusses this question and gives certain statistics relative to the disease among the two races. He does not think the blacks especially predisposed to the disease—outside of matters of habits and environment. The methods to pursue in limiting an infectious disease like tuberculosis should be directed toward increasing the strength and vitality of the individuals of the race, thereby rendering their tissues an unsuitable soil for the invasion and propagation of the specific germs of the disease, and in preventing his exposure to the infective agent, as by the isolation of those already afflicted, and by destroying the organisms causing the disease. A strong plea is made for public support of sanatoria.

*Medical News, October* 3, 1903

**The Obstetric Significance of Retrodisplacements of the Uterus.**—Samuel M. Brickner states that in public and private practice the average of posterior displacements of the uterus is about the same, a little less than 20 per cent. Sterility on the part of the woman with a retroflexion or retroversion is a symptom which often brings her to the specialist. Retroflexion may also arise from trauma during childbirth, from excessive or unusual exercise, or from the involvement of the sacrouterine ligaments. Bicycling to excess is productive of this condition. The puerperal infections involving the sacrouterine ligaments, surrounding them with adhesions as in a posterior parametritis, are responsible also for the causation of retrodisplacements. Prophylaxis is the best treatment, and consists in compelling the patient, after the fifth day postpartum, to lie on her abdomen daily from one to two hours, or if she cannot do this, she should at least lie on her side for an equal length of time. Puerperal women must not remain too long in the dorsal position. It causes many of them acute, and even chronic, pelvic disease.

**Treatment of Migraine.**—B. K. Rachford presents a siphon formula which he prescribes for his patients: Sodii sulphatis (dry), 30 grains; sodii salicylatis (from wintergreen), 10 grains; magnesii sulphatis, 50 grains; lithii benzoatis, 5 grains; tincture nucis vomicæ, 3 drops; aquæ destil. to make 4 ounces. This prescription is made in large quantity by a reliable pharmacist and then sent by him to a mineral-water factory to be put up in siphons and charged with carbonic acid. From one-quarter to one-half glass of this medicine is taken each morning half an hour or more before breakfast. The siphons are sold on prescription at fifty or sixty cents each. This prescription may be given for an indefinite time without losing its great therapeutic value or producing disgust for it on the part of the patient. When combined with proper dietetic and hygienic treatment in the relief of migrainous symptoms, the results of this medication are remarkable. Patients under this treatment often go through the winter months without a single attack of migraine. These patients should not eat too much. They should partake sparingly, or not at all, of coffee, alcohol, and red meats. Sweets should, for a time at least, be almost if not altogether eliminated from the diet. They may be allowed milk, eggs, fish, oysters, white meat of poultry, cereals, fruits, and well-prepared vegetables, unless some digestive trouble excludes one or more of these articles from the diet. Exercise in the open air is very important. All kinds of outdoor athletic sports are valuable. General massage is to be advised in the early treatment of feeble patients. The Turkish and vapor baths and hot alkaline tub baths are beneficial especially to robust patients. They are more efficacious when accompanied by copious draughts of water and followed by general massage.

*New York Medical Journal, October* 3, 1903.

**A Form of Rational Treatment for Corneal Ulcers.**—W. L. Phillips advises the use of suprarenal extract to contract the arteries of the conjunctiva and iris, antisepsis of the conjunctival sac by means of boric acid, and the building up of the lymph corpuscles to a healthy condition to bring about resolution. For the latter purpose he advises a hypodermic solution of nuclein, 5 per cent. Finally, all contributing causes, as adenoids, turbinal enlargements, caries, etc., must be removed. The histories of several cases thus treated are given.

**Essential or Idiopathic Spasm.**—W. C. Fisk gives the notes of a case of this neurosis, sometimes called intermittent tetany or tetanilla. The patient was a man who was strong and robust, but of neurotic habit, having been affected since childhood with attacks resembling *petit mal*. On one occasion he had an attack of the nature mentioned in the title. For a minute he would be calm and cheerful and chat with those about him, and then would come a spasm that would lift him up in bed, or turn him over on his side, or bring his legs up to the perpendicular, or arch his back so that he rested on his head and heels. The spasms were confined to legs, arms, and abdomen, and were at first bilateral, later unilateral. No trismus, facial tremor, or spasm of glottis. Between the attacks he felt absolutely well, with the exception of excusable nervousness over his affliction and the not knowing how soon another jerk of his body would come on. No fever, no headache—and the only pain he complained of was great soreness of his bowels. Subcutaneous injections of hyoscine hydrobromide brought the condition under control, $\frac{1}{100}$ gr. being placed in the soft tissues of the flank.

**Growths of the Male Urethra, with Report of Three Cases.**—The cases are reported by J. E. Morrow. Case 1 was that of a man forty-nine years old. The principal symptom was hemorrhage. With snare, some twenty fibrous nodules were removed, one came away spontaneously, and others were removed by caustic solutions. The urethra was dilated behind the growths, and the continuance of sexual relations after the obstruction had begun to be experienced caused a chronic seminal vesiculitis. Removal of the growths gradually restored the normal conditions. In Case 2, a man of thirty-one, a growth was found by the urethroscope in the prostatic portion near its junction with the membranous portion. This was removed with forceps, the growth being a fibroma. In Case 3 the forceps were also used, the growth being in the prostatic urethra about one inch from the bladder and easily removed, but it was so badly lacerated by the blades of the instrument that microscopical examination was impossible. The author summarizes the methods of treatment as enucleation with knife, scissors, cautery, loop strong astringents or caustics.

*American Medicine, October* 3. 1903.

**The Complications of Hypertrophy of the Pharyngeal Tonsil.**—George B. Wood presents two groups of complications of hypertrophy of the pharyngeal tonsil: the mechanical and the infectious; but these two groups are generally more or less combined in the production of the clinical symptoms. Mouth-breathing is an almost purely mechanical complication, but it may produce conditions which make a ready soil for infection. Skeletal deformities, the most prominent of which are narrowing of the alveolar arch of the upper jaw and so-called "chicken breast," are often due to mouth-breathing. The most serious complications due to the pharyngeal tonsil are the otitic disturbances. The writer has tabulated the chief subjective symptoms of 149 patients with this affliction. Nasal discharge or recurrent attacks of coryza were present in about 52 per cent. Some form of ear trouble was found in 42 per cent. There were symptoms of nasal obstruction in 78 per cent. Headache occurred in 19 per cent. When a number of such symptoms are present, a tentative diagnosis can be made in the majority of cases.

**Surgery of the Upper Right Quadrant of the Belly.**—J. F. Binnie enumerates the structures and organs of special importance in this pouch, or its boundaries, as gall-bladder and ducts, duodenum, pancreas, and part of stomach. Attention is most commonly drawn to the right upper quadrant of the abdomen by gallstone disease. In the majority of cases ,especially in those seen fairly early, the phenomena of infection are not very threatening. Biliary lithiasis in many cases gives rise to many grave complications, difficult to diagnose, but susceptible of great improvement or of cure by early surgical intervention. In themselves, gallstones, except when escaping through the duct, are more or less innocuous, it is the cholecystitis and cholangitis to which they predispose and the complications therefrom which are dangerous and disabling. The symptoms of cholangitis and cholecystitis may be absolutely identical with those of cholelithiasis. The common bile duct passes behind the first segment of the duodenum, then along a groove on the posterior surfaces of the head of the pancreas. When gallstones pass into or through the lower parts of the common duct they are liable to injure the delicate tissue of the neighboring pancreas, and so cause obstruction to the outflow of pancreatic juice. As to operative treatment in affections of the gall-bladder, when it is the seat of phlegmonous inflammation, there is no doubt as to the propriety and urgency of removing it and obtaining drainage of the hepatic duct. The writer then quotes the opinions of various authorities as to the propriety of operation in various conditions.

*The Lancet, September* 26, 1903.

**A Case of Puerperal Septicæmia Treated by Antistreptococcic Serum.**—J. M. Mackenzie and W. B. Blandy give notes of the case of a primipara who passed through a normal labor, but was probably infected by a midwife. The usual douching failed to relieve the condition, and 10 c.c. of the serum were injected between the scapulæ. A few minutes after the injection of serum the pulse was noticed to improve in tone and tension, and had a greater volume; probably the improvement in the pulse was aided by ergotinin, which was solely given to aid uterine contraction, and so, if possible, to diminish the area for septic absorption. The administration of serum was adopted fairly early. Soon after each injection the temperature dropped, the pulse improved, and in two or three hours there was an improvement in the appearance of the patient with a corresponding sense of comfort and well-being. But it cannot be said that this improvement lasted for more than thirteen or fourteen hours. As in other cases in which the authors have used antistreptococcic serum, the dose had to be repeated daily in order to keep up the favorable effects.

**A Case Presenting Signs of Pulmonary Stenosis During Life, Unexplained by the Necropsy, with Some Remarks on Diagnosis.**—The case is reported by W. L. Ascherson, and was that of a man of twenty-eight years. The existence of diarrhœa, albuminuria, and mental hebetude suggested uræmia, while the character and position of a heart murmur heard seemed to point to stenosis of the pulmonary artery. The patient died of acute pulmonary œdema passing over into semi-coma. Autopsy showed the pulmonary artery in every way normal, but the kidneys were in a state of chronic parenchymatous nephritis undergoing contraction. No cause could be found for the murmur heard during life. The author found no growth or aneurysm within the mediastinum to press upon the pulmonary artery and to cause stenosis of its lumen, nor was the left lung in any way retracted. Two facts revealed by the necropsy are, perhaps, worthy of mention. The first relates to the position of the heart, the antero-posterior axis of which was more transversely placed than normally. In such a position the shoulder, so to speak, of the heart would occupy a higher position in the chest and also be rotated nearer to the pulmonary artery. The force of ventricular action would be then at a better advantage to compress it, any hypertrophy tending to enhance the probability of such a result. The altered position of this portion of the heart might also be supposed accountable in some measure for the abnormal dulness found in the first and second spaces. The second point has relation to the undue hypertrophy of the septum. The septum is described as bulging into the cavity of the conus arteriosus. Might not the presence of such a bulging be a cause of stenosis, asks the author, if not of the artery itself, at any rate of the ring and conus behind it? Which of these two facts, or whether either of them, played any part in producing the murmur heard during life it is impossible to determine on the evidence of a single case.

**Remarks on Three Cases of Acute Intestinal Obstruction.**—The cases are reported by T. C. English. Two of the three were saved by operation. The paper is presented to extol the merits of saline irrigation in abdominal operations. The author claims for this procedure the following advantages: (1) Distension of the intestines is usually greatly diminished, and this is a factor of utmost importance, both in regard to the direct effect upon the patient and the ease with which the necessary manipulations are carried out. During the course of the operation the exposed intestines are very liable to become dry and chilled, and then rapidly lose their power of absorbing the gases which are being produced, and so distension already existing is increased. A dry intestine must necessarily be a distended one, the two terms becoming synonymous. Saline irrigation will keep the intestines both warm and moist. (2) Shock, which always attends these operations, is diminished by the free absorption of saline fluid. The effect on the pulse and respiration very rapidly shows itself, and there is the further advantage that several pints in this way may be more quickly introduced into the circulation than by other methods. (3) Thirst, which is one of the most distressing features after abdominal operations, is undoubtedly diminished as a result of the free absorption of fluid. (4) The influence of irrigation upon the subsequent formation of adhesions is an important point. The frequency with which these peritoneal adhesions give rise to chronic abominal pain is well known. When there is a likelihood of peritoneal adhesions following, the best way of minimizing or preventing them is to leave as much fluid as possible in the peritoneal cavity. The intestines are thus rendered, as it were, more slippery, and, moreover, smaller areas of peritoneal surfaces will be in contact with each other, owing to the presence of the fluid. The drier the peritoneal surfaces the more likely are they to adhere and to cause subsequent trouble. In certain cases, however, the formation of adhesions may be the best thing for the patient, and then irrigation should be avoided. So, too, if there should be free oozing from adhesions or raw surfaces, irrigation will tend to maintain and to increase the bleeding. (5) Renal secretion is greatly increased, and thus many of the toxic products circulating in the blood are eliminated through the kidneys.

*British Medical Journal, September* 19, 1903.

**The Pathology of Acute Rheumatism and Allied Conditions.**—E. W. Ainley Walker and T. Henry Ryffel have confirmed the observation of Triboulet that a particular microorganism is constantly associated with acute rheumatism. These writers have given the name "micrococcus rheumaticus" to this organism, since it presents certain definite points of difference from the other members of the streptococcus group. With regard to the origin of formic acid these investigators believe it to be formed by the microorganism by the oxidation of sarcolactic acid into formic and acetic acids. In most cases the formic acid has been separated as a sodium salt, and has been subsequently identified by the usual chemical tests. It may also be separated as an insoluble iron salt. The connection of formic acid with the activity of the rheumatic micrococcus is of considerable interest in relation to the evidence of country folk-lore, since it is currently alleged that persons who keep bees, and are thus often subjected to the action of formic acid, are peculiarly insusceptible to rheumatism. There are already indications that the beneficial action of salicylates in rheumatism may find a simple chemical explanation.

**The Probable Modus Operandi of the Parasites of Malignant Disease.**—J. H. Whelan concludes that the parasites enter and attack the epithelial cells only. They do not destroy the epithelial cells, at least at first, but dominate them and live with them symbiotically. They stimulate these cells to inordinate proliferation, and wean them entirely from their allegiance to their commonwealth. The primary tumor is formed. Traitors are proverbially their country's bitterest foes, and these misguided cells prove no exception. They become the contented helots of the parasites. Detachments of the renegade cells enter the lymphatics, carrying their masters with them, and found colonies wherever they can succeed in making a lodgment—secondary tumors. The renegades batten and fatten at the expense of the other members of the commonwealth, and the parasites batten and fatten by the aid of their helots. The commonwealth gradually becomes poisoned by the combined excreta of the parasites and the renegades. It is preyed upon and obstructed by the alien settlement and colonies. Disorganization, decay, and dissolution follow. The stroma of cancer is but the unsuccessful efforts of the connective tissue cells to isolate and combat the enemy. Sarcomata are probably caused by a different species of protozoal parasite to that of cancer. It probably attacks connective tissue cells, and these only, hence the absence of the distinctive fibrous stroma. Its colonial enterprises are made through the blood circulation.

*British Medical Journal, September 26, 1903.*

**The Use of Retinal Extract in Atrophic Retinæ.**—Robert W. Doyne thinks that the results from the use of retinal extract seem to point to the presence of some physiological principle such as is found in the case of the thyroid gland. Ordinary retinal extract or retinæ preserved in glycerin are of comparatively little value as compared with fresh retinæ. Unfortunately, an obstacle to this treatment is its expense. The dose is equivalent to from six to ten retinæ a day. In the great majority of cases the improvement has been marked and definite. The remedy seems to act by bringing out any potentiality that may remain in the atrophic retinæ. The renewed function has been counteracted by the action of too intense daylight. The writer has seen excellent results in cases of old choroiditis and cases of damaged and thinned retinæ of high myopia.

**Subconjunctival Injections of Tuberculin T. R. in the Treatment of Interstitial Keratitis.**—A. Darier relates the case of a girl of thirteen years. There was an absence of all signs of syphilis. A variety of treatment was employed for the eyes. The sight of the right eye had been completely destroyed and the year following the left eye became affected. Finally, on the right side was given a subconjunctival injection of tuberculin. The local reaction was most violent, but there was not the least rise of temperature. For eight days there was intense chemosis, etc., and pannus developed. A considerable number of injections were given till the cornea was transparent enough to allow the contents of the anterior chamber being seen, and an abundant exudation on the back of Discemet's membrane. The fluid in the anterior chamber was so viscid that it could not be aspirated. Posterior synechiæ were present, and an iridectomy was done. About three months later the vision had returned.

**An Operation for Ptosis.**—H. Collen Ensor devised and performed the following operation on a case of complete unilateral ptosis. The patient was a girl of nine years. The eyebrow was shaved and slightly raised, and an incision was made down to the periosteum covering the supraorbital ridge from the internal to the external angular process. A second incision was made through the skin only from the extremities of the former incision and below it, so that a portion of the skin, about 5 mm. broad at the inner side, and 7 mm. at the outer side, could be removed with scissors, as here the skin was more abundant, and the occipitofrontalis did not act so powerfully. Pacquelin's cautery was then applied to burn the tissues at the upper part of the wound, thus charring the tissues to the bone along its whole extent, the orbicularis palpebrarum also being burnt to weaken the muscle. The wound was dressed, and allowed to granulate, and it healed in three weeks. To produce a little more effect the operation was practically repeated later on. The result was excellent. The appearance is far more symmetrical than formerly. The scar is hidden, being immediately below the hair of the eyebrow. The formation of a fixed groove under the eyebrow was accomplished in place of the appearance of vertical bands produced by the constant action of the occipitofrontalis muscle.

*Münchener medicinische Wochenschrift, September 15, 1903.*

**Generalized Lymphœdema of the Skin Due to a Suppuration of a Large Number of Superficial Lymphatic Glands.**—Arnold Sack's patient had a permanent lymphœdema of the skin. This arose as the result of the destruction by suppuration of the majority of cutaneous lymphatic glands throughout the body. In addition, the patient was subject to repeated attacks of erysipelas. The case shows that the superficial lymphatic vessels and glands play an important part in disposing of the superficial lymphatic circulation, and that the venous system is not the chief channel through which this is accomplished, as has been supposed by Unna. Furthermore, the importance of the superficial lymphatic system, in acting as a barrier to bacterial infection, is emphasized, as shown by the repeated attacks of erysipelas to which this patient is subject.

**Innervation of the Bladder and Large Intestine.**—Eduard Hirt reports a case which confirms Müller's view that the reflex center for the evacuation of the bladder and large intestine is not exclusively located in the spinal cord, but that impulses may also be conveyed through the sympathetic to the brain. In this case there was a lesion of the cord above the supposed spinal reflex center, the action of which would thereby be destroyed. At first there was no evacuation of the bladder or large intestine. Some two weeks later a reflective evacuation of the bladder and intestine, at stated intervals, set in, and this continued until death. Autopsy reveals the above spinal lesion and confirmed the supposition that the spinal bladder and intestine reflex centers were entirely destroyed. In such cases the impulse for evacuation is supposed to pass according to Rehfisch's observations, through branches which join the first to third sacral nerves with the sympathetic and hypogastric plexus.

**Lime "Adsorption" by Animal Tissues with Respect to a Modern Theory of Rickets.**—Meinhard Pfaundler places bone dust in a neutral solution of calcium chloride and finds that at the end of a given time there has been a decided loss of the solution in calcium. Further observation shows that this process is neither entirely chemical or mechanical in nature, but stands midway between these two, and may be designated as an "adsorption." Such a process is elective—that is to say, it occurs only between certain ions and certain forms of tissue. That it is the only way in which lime is assimilated by the body is not to be maintained, but that it is one of the steps in the process cannot be doubted. In newly-formed osteoid tissue there is no special affinity for the inorganic components which subsequently enter into the composition of the bone, but as time advances changes take place in such tissue and such an affinity appears. In other words, for "calcification of bone" a certain especial heteroplasia of the osteoid tissue is necessary. Observation shows that rickets is not due in any way to the deficient feeding of lime, and that the adsorption of lime is in no way reduced. It would seem probable, therefore, that the deficient calcification of the bone is due to a failure in the second step in the process of lime assimilation—that is, a failure of the requisite heteroplasia of the osteoid tissue above referred to. This may possibly be regarded as an autolytic process, and is an introductory step in the retrograde metamorphosis of fully-formed protein substances, which is evinced in various tissues throughout the body other than osteoid.

*Berliner klinische Wochenschrift, September 14 1903.*

**Fever and the Excretion of Sugar.**—Friedrich Richter, by a series of experiments upon rabbits, shows that the disappearance of glycosuria in diabetics during fever is not due to the high temperature *per se*, but to the bacterial infection which is the cause of the fever. If rabbits, in which fever has been produced by brain puncture, under aseptic precautions, are given injections of adrenalin, sugar regularly appears in the urine, although the temperature of the animals constantly remains high. On the other hand, if the fever has been produced by bacterial infection (streptococci were employed), no glycosuria occurs as the result of similar injections. The disappearance of the sugar from the urine is probably due to the action of the metabolic products of the infecting microorganisms within the body.

**The Poison Components of Diphtheria Toxins.**—P. Ehrlich says that the diphtheria bacillus produces different kinds of toxins, especially toxins and toxons. The avidity of diphtheria toxin to antitoxin is very great. The deviations from the limit of avidity are not to be explained by the supposition of a single toxin of weakened affinity, but by the fact that in the toxic bouillon different substances of a toxoid character are present. Furthermore, the different avidity of these toxoids cannot be accounted for upon the basis of a single toxin, originally present in the bouillon and which has lost its affinity for the antitoxin in varied degrees, but by the supposition that there were always present in the bouillon different toxins of different avidities. No change in the haptophore group is present in toxoid formation. The absolute number of combining units present in the immunity unit is 200.

**Nasal Dysmenorrhœa.**—Erich Opitz records a case which he thinks adds increased evidence to the view that there is a distinct variety of dysmenorrhœa which should be called "nasal." The patient was twenty-one years of age and applied for treatment for nasal obstruction. At this time nothing was mentioned by the patient concerning any menstrual disturbance, nor was the fact that she suffered from dysmenorrhœa known to the attending physician. An operation was performed and the nasal passages freed. A short time thereafter the *mother* of the patient stated that since the operation violent attacks of dysmenorrhœa from which the patient suffered since she began to menstruate had entirely disappeared. Not many months subsequent the dysmenorrhœa reappeared. An examination of the nares showed that obstruction to a certain degree had recurred. The connection between the nasal appearances and the menstrual disturbance was then explained to the patient and a second operation upon the nares undertaken. This operation was not as successful as the first, but although the patient was not aware of this fact, the attacks of dysmenorrhœa continued with their original intensity. Surely there can be no thought that in this case dysmenorrhœal attacks were influenced by suggestion, and it must be regarded as a genuine case of nasal dysmenorrhœa.

# Society Reports.

## AMERICAN ELECTROTHERAPEUTIC ASSOCIATION.

*Thirteenth Annual Meeting, Held in Atlantic City, N. J., September 22, 23, and 24, 1903.*

DANIEL R. BROWER, M.D., OF CHICAGO, PRESIDENT.

**Special Report to the Medical Record.**

*Tuesday, September 22—First Day.*

THE association was called to order in the Hotel Windsor. Although there was a goodly number in attendance, a tinge of sadness was noticeable in the proceedings because there was a feeling of personal loss in the death of their genial and indefatigable coworker, Dr. Robert Newman, of New York, who was called away while busily engaged in making the final arrangements for the meeting. It need hardly be said that the resolutions relative to this event represented more than a mere formality.

**President's Address.**—Dr. DANIEL R. BROWER of Chicago, in considering the welfare of the association, made the suggestion that it should unite with the American Medical Association or become one of the component societies of the Congress of American Physicians and Surgeons. Such a step would offer an excellent opportunity for interesting the general practitioner in electrotherapeutics.

**New Electrodes.**—Dr. FRANCIS B. BISHOP of Washington, D. C., described an electrode, for the static or high-frequency currents, which was made up of a bottle filled with water and having a piece of wire passed down into the liquid as a conductor. He had also constructed a useful electrode from a child's whisk broom. A long wooden handle was attached to the broom, and provided with a sliding brass collar. It gave a very soft and diffused current with the static spray.

Dr. MORRIS W. BRINKMANN of New York had devised a series of electrodes made of glass tubes, both straight and curved, which were filled with plumbago or crushed electric-light carbon. He also used electrodes made of glass tubes having very thick walls and a very small caliber. These were filled with mercury.

Dr. WILLIAM B. SNOW of New York expressed a preference for electrodes of white maple wood tipped with pieces of various shapes. He also employed a series of vacuum tubes of various sizes and shapes suitable for use not only on the surface of the body but in its various cavities.

Dr. G. BETTON MASSEY of Philadelphia exhibited some platinum-iridium needles which he made out of platinum-iridium wire obtained from dental supply houses. Pieces of suitable length were sharpened at one end by a jeweler's file, and fastened into a handle of hard rubber, being connected with No. 30 conducting wire. They might be very delicately insulated by heating them and melting on hard rubber from a piece half an inch thick. Although this insulation did not last more than half an hour, it could be so readily and finely applied that it was of much value.

**An Experiment in Cataphoresis.**—Dr. FRANCIS B. BISHOP of Washington, D. C., described some experiments that he had made, and which he believed demonstrated that the high-frequency current, as transmitted through a transformer, would penetrate glass and transmit through the glass metallic and liquid substances. He made use of a Piffard coil excited by a Toepler machine of twelve revolving plates. A solution of starch was placed between two clean glass plates measuring 8 by 10 inches, and a sealing of paper, fastened with starch paste, was then applied to the glass plates. A solution of potassium iodide in glycerin was placed on the center of the upper glass plate, and the lower glass plate was placed upon a metallic surface and connected with the earth. The spark employed came from one side of the Piffard coil, and was directed upon the iodide solution. In a few minut iodide of starch was formed. In order to see if the proc could be reversed, Dr. Bishop began treating some je cases by applying iodide of potassium solution extern and applying the high-frequency current by means of hollow glass electrode, filling the latter with a solution starch. After having used this electrode for several we small specks of iodide of starch could be seen floating the fluid.

Dr. T. A. PEASE of Norwood, N. Y., said that he been able to confirm the last observation described.

Mr. R. G. BROWN thought Dr. Bishop had been mis and that the result would have been different if the glass plates had been hermetically sealed.

Dr. W. B. SNOW remarked that workers with vacu tubes knew well that the current passed through the gl

Dr. ALBERT C. GEYSER of New York was disposed think that the blue reaction obtained was not due iodide of starch but to the action of the ozone genera

**Committee on Constant Current Generators and C trollers.**—Dr. WILLIAM J. HERDMAN of Ann Arbor, Mi presented this report. He said that the constant cur was now obtained for electrotherapeutic work from dustrial dynamo currents all over the world, and was with much satisfaction; but in some places there was such dynamo current available, and, moreover, it not portable, and, hence, could not be used at the bedsi The dry cell had partially solved this problem. The vestigations of the committee showed that the consta and efficiency of the dry cells found upon the mar differed very considerably. The drain upon their chemi composition was not heavy, but it was intermittent irregular, the demand being considerable at times, follow by more or less prolonged intervals of rest. For th years they had experimented with such cells in laboratory, simulating as closely as possible the act conditions found in medical practice. Some of results of these tests had already been submitted to association, and the present report showed the resu obtained with a new and very promising candidate favor among the dry cells on the market.

**Electrotherapy as a Specialty.**—Dr. ALFRED W. BAYL of Buffalo presented this paper. He dwelt upon the ne for special preparation and compared the work done he and in the hospitals abroad. The author advised t exercise of caution in giving a prognosis until the effe of the current had been studied in the individual case.

Drs. A. D. ROCKWELL and W. B. SNOW of New Yo objected to making electrotherapeutics a specialty.

**The Effects of the Secondary Static Currents in Removi Albumin and Casts from the Urine.**—Dr. BOARDMAN RE of Philadelphia was the author of this paper. He sai that probably one-fourth of his cases of gastrointest n disease of long standing had had hyaline casts and albumi in the urine; nevertheless, many of them had prove amenable to appropriate dietetic and other treatment These cases probably belonged in the category of toxi nephritis, and resulted from the injurious action of th toxins of indigestion upon the kidneys. He proposed t call such cases autotoxic nephritis, and was of the opinio that if they were neglected or were wrongly treated they might lead to permanent organic disease of the kidney His experience in the treatment of these cases had *not* been satisfactory until he had resorted to the use of static electricity, as suggested by Dr. A. D. Rockwell. During the past year he had observed eighteen cases of this kind. Four illustrative cases were reported, in three of which static electricity successfully controlled the albuminuria. So far as his experience had gone, the faradic current had not proved so useful in these cases as the static current In most cases he had made use of the static wave current, but he was inclined to think now that the static *induced* current was the best form of electricity to employ in this class of cases. He had had urine analyses made just

# News of the Week.

**Steps Looking to Medical Unity in New York State.**—A special meeting of the Council and Fellows of the New York State Medical Association was held in the New York Academy of Medicine on the afternoon of October 1, 1903, to consider overtures from the Medical Society of the State of New York, looking to a union of the two State Medical organizations. The following letter addressed to Dr. F. H. Wiggin, President of the New York State Medical Association, was read:

SYRACUSE, N. Y., May 28, 1903.

"MY DEAR DOCTOR: At the last meeting of the Medical Society of the State of New York the Committee on conference appointed to confer with the similar committee of the New York State Medical Association, after making its report, was continued and instructed to await the action of the American Medical Association at New Orleans before considering further the methods of amalgamating the regular profession of the State of New York. At a recent meeting of the American Medical Association radical action was taken removing the obstacle which prevented unification. Appreciating the fact that no further barrier stands in the way of uniting the profession of the State of New York into a single State society, the committee representing the Medical Society of the State of New York would respectfully ask the New York State Medical Association that further conference with its representatives be arranged with the object of speedily settling upon a definite plan which shall form the basis for amalgamation of the two existing bodies. In making this request the committee representing the Medical Society of the State of New York assures the Association of its earnest desire to increase the influence of the State profession by the action suggested; that it would further state to that body that it is ready to suggest to the Medical Society of the State of New York that it amend its charter to continue the consolidated and amended chapter 138 of the laws of 1806, chapter 94 of the laws of 1813, and chapter 452 of the laws of 1900 for the purpose of cultivating and advancing the science of medicine, the promotion and protection of public health, and the establishment of a death benefit fund for the dependents of the members of the Medical Society of the State of New York. That it feels justified still further in assuring the association that it will recommend to the State Society the method of organization founded upon the plan suggested by the American Medical Association and considered by the joint conference when in session in April, 1902, and that all other matters of detail, which must be considered before final action can be taken by the respective societies, must, of necessity, become subjects for conference. The committee asks for careful deliberation in conference that both the society and the association may in the near future be able to present completed and satisfactory plans to the State bodies for ratification."

Signed, Henry L. Elsner, Chairman; A. Jacobi, A. Van Der Veer, George R. Fowler. The only member of the committee who did not sign was Dr. Frank Van Fleet.

In his reply to Dr. Elsner, Dr. Wiggin wrote, under date of June 10, 1903: "MY DEAR DOCTOR: I have received your communication of the 28th requesting appointment by our association of a committee to confer with your committee relative to plans for uniting our State bodies, signed by yourself, Drs. A. Jacobi, A. Van Der Veer, and George R. Fowler, and I shall take pleasure in presenting to our council at the earliest practicable moment for consideration and such action as they may see fit to take on it, as, under our constitution and by-laws, matters of importance are so referred."

(Signed) FREDERICK HOLME WIGGIN,
Pres. N. Y. State Medical Association.

The following preambles and resolutions were then introduced by Dr. Joseph D. Bryant and were unanimously adopted:

"*Whereas*, The members of the New York State Medical Association desire a union of the medical profession of the State of New York, and,

*Whereas*, It is deemed expedient for the attainment of this purpose to make further effort to bring together the New York State Medical Association and the Medical Society of the State of New York under the name of The Medical Society of the State of New York:

*Resolved*, That a committee of five be appointed by the Chair, and said committee is hereby empowered to do whatever is necessary and expedient to bring such a union in a just and equitable manner, and

*Resolved*, That the committee so empowered may confer, coöperate, and unite with the committee of the Medical Society of the State of New York for the purpose of forming such union of the two medical organizations; and

*Resolved*, That a copy of these resolutions be transmitted to the secretary of the Medical Society of the State of New York with the request that their conference committee be granted similar powers."

*Resolution of the Cortland County Committee.*—At a meeting of committees from the Cortland County Medical Society and Cortland County Medical Association, held at the office of Dr. Higgins on Friday, September 4, 1903, the following resolution was adopted:

"*Resolved*, That, as about thirty-five or forty of the members of the Cortland County Medical Society are members of both the society and association, we believe that we express the sentiment of nearly all the profession of the county, in the desire for the harmonious union of the two medical organizations of the State, since we believe our influence and power in the State in obtaining needed legislation and preventing the enactment of harshful laws, would be greatly enhanced thereby, and we recommend that all proper measures be taken to bring about this end.

Committee for Society, F. W. Higgins, H. T. Dana, J. W. Whitney.

Committee for Association, S. J. Sornberger, C. D. Ver Nooy, F. D. Reese.

*Resolution of the Onondaga County Society.*—The following was adopted June 2, 1903:

"*Resolved*, That the Onondaga County Medical Society, which has always remained loyal to the State body, because of the recent action of the American Medical Association, paving the way to unification of the regular medical profession of this State, believes that the time has come when the two State bodies shall become united in a single body, and that, the Medical Society of the State of New York; that both the society and the association shall at once approach this scheme in a spirit of conciliation, willing to make such concessions as each body can consistently make, and that a copy of this resolution be forwarded to the President of the Medical Society of the State of New York, the President of the New York State Medical Association, and to the Committee on Conference."

A. S. HOTALING, Secretary.

**The Cancer Research Fund of the General Memorial Hospital.**—In the early part of the present year,

Mrs. C. P. Huntington gave the General Memorial Hospital of New York a fund of $100,000—the income of which is to be devoted to research work bearing upon the etiology and treatment of cancer. This fund is under the direction of a special committee of the Board of Managers, composed of Drs. William T. Bull, William B. Coley, and Francis R. Kinnicutt and Messrs. A. M. Huntington, George C. Clark and John E. Parsons (ex-officio). Dr. Bull was appointed Chairman of the Committee and Dr. Coley Secretary. The Loomis Laboratory has offered laboratory facilities free of charge, and the work for the coming year began October 1. Dr. B. H. Buxton has the general direction of the laboratory work and Mr. S. P. Beebe, recently from Professor Chittenden's laboratory at Yale, will do most of the experimental work. The present plan is to investigate the physiologicochemical side of the problem which, as yet, has received little attention. The members of the committee fully realize the great difficulties surrounding the etiology of cancer and have little hope of immediate results, but they believe that an effort to remove some of these difficulties may tend to hasten the final solution of one of the greatest problems of modern medicine.

**The New Child Labor Laws.**—Three child labor laws of far-reaching importance went into operation on October 1. They are the Hill-Finch measures prepared by the Child Labor Committee, and passed last winter by the New York State Legislature in response to the appeal of settlements, churches, medical societies, and philanthropic organizations throughout the State. A very large share in the enforcement of the new laws devolves upon the Health Department of this city. All employment certificates are issued to children by this department, and the most important changes in the laws relate to the conditions under which these are granted. According to Dr. Lederle, Commissioner of Health, the new laws do not affect the age at which children may begin to work. They merely require parents to supply some real evidence that the child has reached the required age, fourteen years. A copy either of a birth or baptismal certificate or of some other religious record or of a passport must be filled when application is made. Hitherto the parents word under oath has been accepted regarding the child's age, and the result has been merely to put a premium on perjury. This more rigid system is successfully used in Massachusetts and Connecticut. Another important change in the law is its extension to cover telegraph, messenger, and delivery boys, together with all children employed in business offices, restaurants, hotels, and apartment houses. The law has applied hitherto only to factories and stores, and thousands of children in these other employments have been allowed to begin work with no questions asked by the authorities as to their age or schooling. This has been especially unfortunate in the case of telegraph and messenger boys, whose occupation subjects them to the most serious moral temptations. Proprietors must now require certificates of all children they employ under the age of sixteen, and they must see to it that such children do not work longer than nine hours a day. According to the Secretary of the Child Labor Committee, Mr. Fred S. Hall, New York has now the best laws on this subject in the United States.

**The Medical Society of Virginia.**—The thirty-fourth annual meeting of this society was held at Roanoke, on September 16 and 17, 1903, under the presidency of Dr. J. N. Upshur of Richmond. About three hundred members were in attendance. The election of officers resulted as follows: *President*, Dr. Joseph A. Gale of Roanoke; *Recording Secretary*; Dr. Landon B. Edwards of Richmond; *Corresponding Secretary*, Dr. John F. Winn of Richmond; *Treasurer*, Dr. Robert M. Slaughter of Theological Seminary; *Orator*, to deliver the annual address to the public and profession, Dr. William S. Gordon of Richmond. The next annual meeting will be held in Richmond, the date to be announced latter by the Executive Committee, of which Dr. P. A. Irving of Richmond is chairman.

**An International Congress of School Hygiene** will be held at Nuremberg, Germany, on April 4-9, 1904. All persons interested in this subject are eligible to membership, after approval by the local committee. The membership fee is $5. Papers and discussions may be in any European language, but the use by preference of English, French, or German is urged. A copy of every paper and formal communication to be presented to the Congress, together with an abstract in one of the three preferred languages (if the paper is in any other language), must be forwarded in advance to the Committee on Organization. The work of the Congress will be divided into general sessions and special sessions. The special sessions will be held on three mornings and every afternoon. Monday, Tuesday, and Friday mornings will be reserved for the general sessions, when addresses without debate will be delivered on points of common interest, official addresses will be delivered, and the business affairs of the Congress transacted. There will be ten sections, as follows: (1) Hygiene of the school building and its appointments. (2) Hygiene of boarding schools. (3) Methods of hygienic research. (4) Hygiene of the mental education. (5) Hygienic instructions for masters and pupils. (6) Bodily training of pupils. (7) Illness, minor ailments, and medical attendance in schools. (8) Children of weak intellect, and schools for their benefit; courses for stutterers, for the blind, deaf, and dumb; schools for cripples. (9) Hygiene of the scholars after school hours, holiday camps, and organization of evening instruction in school-hygiene for parents. (10) Hygiene of the teachers. The honorary presidents of the Committee on Organization in Nuremberg are Dr. G. Merkel and Hofrat Ritter v. Schuh; presidents, Drs. Stich and Glauning; secretaries, Herren A. Därr and Degelbeck. The American members of the permanent International Committee are President Nicholas Murray Butler of Columbia University, Prof. W. T. Porter of the Harvard Medical School, and Prof. John A. Bergström of Bloomington, Ind., University.

**The Philadelphia Society of Tropical Medicine.**—A society has been organized with the special object of preparing students of medicine and physicians for service in the tropical dependencies of the United States, and the following officers have been elected: *President*, Dr. Thos. H. Fenton; *Vice-Presidents*, Drs. James C. Wilson and James Anders; *Secretary*, Dr. Joseph McFarland; *Treasurer*, Dr. E. B. Gleason; *Executive Committee*, Dr. John V. Shoemaker, chairman, and Drs. T. H. Fenton, Judson Deland, R. G. Curtin, Orville Horwitz, and Hobart A. Hare.—*Medical Book News.*

**A New Park on the East Side.**—A public hearing before the Board of Estimate and Apportionment in this city will be held next month to consider a proposition for a public park at Monroe, Market, Hamilton, and Catherine streets. It has been suggested by Mr. Robert W. De Forest, the Tenement

naller, or endogenous moiety, from the detructive etabolism of the nucleins of the body tissues. (3) is the endogenous moiety alone which is increased gout and lithæmia. (4) Gout and lithæmia e mere symptom names for a miscellaneous group chronic toxæmic processes of widely-varied origin, aracterized by the production of uric acid and e urates. (5) By "gouty diathesis" we mean the ssession of a sufficient degree of resisting power the part of the protective cells of the body to pose the entrance of any poison, whatever its aracter or source, with consequent destructive etabolism and production of uric acid, but not equate to neutralize or successfully prevent its sorption. (6) The uric acid of gout, like the phosoric acid which invariably accompanies it, is erely a result and measure of the destructive etabolism of the nucleins of the body cells, chiefly, obably, of the leucocytes, in response to the invan of poisons or toxins, either organic or inorganic. (7) Hence the use of lithia or other "solvent" ents is irrational, and any benefits resulting are to explained on other grounds. (8) As most of the ins setting up this destructive metabolism and sequent uric-acid production are of intestinal gin, diet in gout should be regulated solely with ard to the diminution of intestinal fermentation d putrefaction. (9) As animal foods, from their ch more appetizing and attractive flavors, are t to be indulged in in excess of the oxidative wers of the body their limitation may be found be more frequently necessary than that of vegeble foods, but sugars and starches are also very en at fault. (10) As uric acid and the alloxur up are not toxic, or at best feebly so, and are the cause of gout, the prohibition of foods, en rich in nucleins and purin bases, such as red ats, roe, and sweetbreads, has no rational basis d is clinically of doubtful utility except by dimshing the attractiveness of the dietary. (11) e rôle of the liver in gout is a negative one, being bility to perform its chief normal function as a oison filter," and to absorb or transform into rmless excretory substances the excess of toxins ought to it by the portal vein. (12) The drugs und of value in gout owe their efficacy chiefly their power of checking intestinal putrefaction or preventing the absorption or promoting the mination of its products.

---

### Strong Measures Necessary in Order to Fight Syphilis Successfully.

Dr. Don A. Valdivieso y Prieto read a paper at he International Congress at Madrid in which he rged the need of declaring transmission of venereal sease an offence at law. The author dealt with he subject more especially from the point of view f European nations, where regulations are in force y which it is attempted to control prostitution nd to minimize the danger of contracting venereal iseases. Despite such laws, however, syphilis and sser venereal affections prevail most extensively, nd are an important source of ill health and mortality. Dr. Prieto is of the opinion that the excessive mortality during infancy is largely due to inherited syphilis, and not so much owing to faulty nutrition and insanitary conditions in childhood. The syphilitic taint makes the delicate little frame a suitable medium for the cultivation of all classes of parasites, especially for the tubercle bacilli. In the second stage of childhood, when approaching the age of puberty, the syphilitic is deficient in physical strength, and his tissues have not the normal resisting power to tubercle bacilli. The infected individual passes from a feeble boyhood to a feeble and prematurely old manhood, and at the beginning of his life seeks to make up deficiency of vigor by alcohol. To him the influence of drink when first taken in moderation, on respiration, is most grateful and exhilarating. In a short time he becomes a confirmed drunkard, and in some cases, thinks Dr. Prieto, so far from hastening death, the use of alcohol prolongs the life of the consumptive. While fully recognizing the lethal effects on the people of both alcohol and tuberculosis, the author maintains that it is the hereditary taint of syphilis that predisposes to both diseases.

The evil, syphilis, which is sapping the physical and mental vigor of the population and predisposing to other diseases, remains practically unaffected. All civilized governments seem to think they have fulfilled their duty in this branch of hygiene when they regulate prostitution, but asserts Dr. Prieto, they make no progress in checking the disease. The papers of license contain no identification of the person, neither is isolation of the infected person insisted upon. Besides, the amount of regulated prostitution in large cities is small in comparison to that carried on clandestinely. In existing regulations no steps are taken to prevent the spread of the disease by men, although it is generally recognized that the principal source of contagion is not in brothels or in licensed women, but in men. The author suggests in the interests of the public, that the following rules should be laid down: (1) The law to declare the infection of any person with any form of venereal disease to be a crime. (2) That such crime against the person be punished by indemnification and imprisonment for a period of two years. (3) Where the offender could not indemnify the injured person by bearing the expenses of treatment and so forth, that the term of imprisonment or transportation be increased. (4) That the brothel-keepers be made to indemnify any person infected on their premises or by any of their licensed women, and in case of insolvency of the brothel-keeper, imprisonment or fine shall be enforced.

If carried into effect, the above regulations should have a decidedly deterrent action on the spread of syphilis, for they are assuredly of a sufficiently drastic nature. Physicians in all parts of the world appreciate at its true force the inroads that are being made upon health by the increasing prevalence of syphilis. The disease is omnipresent and, unless crushed by strong measures, will wreak incalculable harm on the human race. In the large cities of the United States syphilis flourishes like the upas-tree, and is as deadly as that member of the vegetable world was once thought to be. No false sentiment or thought of gain must hinder public authorities from boldly grappling with the evil, or the outcome may be disastrous beyond conception.

---

### The Suicide Question.

Professor Bailey of Yale has been making a study of suicide in the United States for the period covering 1897 to 1901. Ten thousand cases were dealt with by Professor Bailey. He finds out of this number that 7,781 males and 2,219 females put an end to their existence, giving a ratio of suicides of males to that of females of three and one-half to one. His statistics show that the period in which *felo de se* is most frequently committed is between the ages of thirty and forty years, closely followed by the

period between twenty and thirty years. Almost two-thirds of the suicides occurred between the ages of twenty and fifty, while the number of married suicides exceeds that of those who are single. The relative proportions, according to the findings of Professor Bailey, are as follows:

| | Males | Females | Total |
|---|---|---|---|
| Single | 3,129 | 926 | 4,054 |
| Married | 3,817 | 990 | 4,807 |
| Widowed | 496 | 183 | 679 |
| Divorced | 137 | 52 | 198 |
| Unknown | 202 | 68 | 262 |
| Total | 7,781 | 2,219 | 10,000 |

"Married men are more prone to take their lives than married women, but more single, widowed, and divorced women commit suicide than men in like conditions. Shooting is the most favorite mode of suicide, and poisoning is a close second. Despondency is the chief cause of suicide, and business losses are more potent factors in driving individuals to the commission of the rash deed than ill health, insanity, disappointment in love, or strong drink. Suicide on account of alcoholism is seventeen times as common among the males as the females, while from business losses the proportion is thirteen to one. Monday is the favorite day for committing suicide, and next comes Sunday. Saturday is the day on which the fewest suicides take place.

Professor Bailey explains these thus: "For those who have endured throughout the week there is pay day at hand, followed by a day of rest. Among the males Monday is preëminently a day for suicide. Females prefer Sunday to Monday. Religious excitement may have something to do with this, but nearly a third of the domestic troubles leading to suicide come on Sunday. Of 10,000 cases, 3,687 occurred in the twelve hours before noon and 5,848 in the remaining twelve hours. Beginning with midnight there is a continuous increase until 6 P.M. The three hours from 6 to 9 P.M. show a falling off, while from 9 o'clock till midnight is the period of greatest frequency."

## Lepers in Northern Nigeria.

Dr. T. J. Tonkin, medical officer of the Hansa Association's Central Soudan Expedition, writes in the August and September numbers of the *Empire Review* of his experiences among the lepers in that part of the Soudan known as Northern Nigeria. . Leprosy is extremely prevalent there—more so, perhaps, than in any other locality of a like size in the world—so that the writer who spent a considerable time among the Nigerian lepers, is able to give valuable information as to their habits and mode of life, and his views with regard to the disease are worthy of close attention.

His opinions respecting the contagiousness of leprosy are in accord with those of Hansen and many other prominent authorities, but he combats the popular notion that the disease is incurable. With respect to this point he says: "Leprosy is supposed to be incurable. Incurable it certainly is, in the sense that at present we are not in possession of any remedy that affects its course as definitely as, say quinine affects that of malarial fever, and iodide of potassium another more common than reputable disorder. It is not incurable in any other sense, however. Recoveries from the disease are by no means of infrequent occurrence. As a matter of fact, it is a rare thing to hear of the actual morbid processes covering a period of more than twenty years. If the patient has survived so long it will often be found that all specific leprous manifestations have disappeared."

The influence of heredity on the spread of leprosy, Dr. Tonkin thinks, is another popular fallacy. He states that, in point of fact, direct heredity has nothing whatever to do with the spr leprosy, and that his Nigerian results bear d on this point. Of all the lepers examined in the Soudan, only 10 per cent. had any taint in their ancestry, leaving 90 per cen must have derived their disease or their te from other sources. Moreover, among the of leper parents, a percentage of less than veloped the disorder.

The writer regards defective diet as pla important part in the development of But he holds that leprosy is a contagious fectious disease, and in the Soudan is spre person to person mainly by the agency of clothes. He maintains that segregatio effectual means of checking the advanc disease and of finally stamping it out. This is, unfortunately, impracticable in the China, or India, but much the same cycle of may be anticipated in these countries place in England and in other lands where was once rife, but where it is now extin civilization progresses and as the countries i leprosy is now prevalent come under the western nations, sanitary methods and a manner of living will, in Dr. Tonkin's drive out the disease.

## The Drug Habit.

The New York *Sun*, October 4, gives an a this subject, which appeared recently in the *Daily News*. The drift of the argument is that the drug habit is largely on the inc Great Britain. Dr. Forbes Winslow is qu an authority for this statement, and inci he narrates some of his experiences when the Chinese quarter of New York. As to th in England, Dr. Winslow declares that it common there, and chiefly among ladies. regard to the increase of the habit in Engla said, "that it had increased very much. A ago as 1872 no less than 356,211 pounds of were imported into England, and if the indu were measured by this standard the decline a of the social system might be confidently predi There has been a great deal of discussion re respecting the increase of the drug habit, both i country and in Great Britain, and it may b with a greater or less degree of certainty that reports have been greatly exaggerated.

**Note on the Discovery and First Use of the St Tube by an American Physician.**—Julius Friedenwal that it is generally believed that two English su Jukes and Bush, are the inventors of the stomach This claim is based on an article published by Jukes London Medical Repository of 1822. That the cr this discovery is due to Dr. Physick there can be no Physick published his original paper, October, 1812. Eclectic Repertory, Vol. III, page 111, under the "Account of a New Mode of Extracting Poisonou stances from the Stomach. By Philip S. Physick, Professor of Surgery in the University of Pennsylv which is ten years prior to the appearance of Jukes' In this paper Dr. Physick gives an account of his use stomach tube in the case of two infants who were po by laudanum. The writer then carefully revie evidence of Physick's priority, and concludes that can be no doubt that he used the tube as early as and that he recommended it for many years in his le to his students, and that in 1812 he published the of successful results of its use in cases of poisoning, the work of Jukes first appeared in 1823.—*Bulletin Johns Hopkins Hospital.*

d after many of the treatments, and had found a ncrease in the excretion of the urea after the treatment, showing that there was a definite action, and that this treatment was something m psychical.

D. ROCKWELL of New York said that he believed xciting circulatory drainage much could be done y of relieving inflammatory action in the tubules ma of the kidney, a condition often spoken of as disease. There seemed to be, however, no sharp marcation between inflammatory and structural f the kidney. Electricity was certainly an agent ing congestion and increasing the blood-pressure omeruli of the kidney, and in this way it improved rition of that organ and, theoretically at least, e glomeruli from the products of inflammation. ld, in this connection, caution against too great n in the treatment of such cases, for it had taken years to secure five cases which, in his opinion, table for electrical treatment. All such cases had ated for periods of from three to eighteen months, had taken the precaution to have the accuracy of ical records vouched for by medical colleagues. ly believed that the method of treatment under on was of value in the milder forms of kidney

WILLIAM BENHAM SNOW of New York expressed rise that Dr. Reed should prefer the static induced wave current, and was disposed to believe that this cause Dr. Reed had not used a sufficiently great gap. Personally, he believed that the wave current give more uniformly good results than the static d, because the latter was more local in its action, oduced less nutritional effect. In treating the back his current he employed a spark gap of from 4 to es, and in obese persons a gap of even 8 inches.

G. BETTON MASSEY of Philadelphia said that some ago he had treated by static electricity a person urine contained a considerable quantity of sugar. eatment had been persisted in for several months, inary examinations had been made from time to Although the effect of the treatment on the quan- sugar was very favorable, the treatment was finally tinued because it was evident that a cure could not ected.

Reed, in closing the discussion, said that it was le that if he had used a more powerful static machine uld have secured better results from the wave current. ished it distinctly understood that he did not claim any of his cases had been cured, but simply that treatment for from one to three months the urine me free from albumin and casts, and that this ap- nt cure had lasted so long as these persons had rved a proper mode of life.

**me Principles upon Which Is Based the Use of Elec- y in Nervous Diseases.**—Dr. A. D. ROCKWELL of New k presented in this paper some theoretical considera- s concerning the manner in which electricity acts n the neurons, and discussed the possible identity of tricity and nerve force.

**-ray and Light in the Treatment of Tuberculosis.**— . RUSSELL HERBERT BOGGS of Pittsburg read this per. He declared that these therapeutic methods uld be placed first among the adjuvant measures in e treatment of this intractable disease, and that, too, thout regard to its location. The author objected to e static machine as a source of the *x*-ray because of its ncertainty and lack of volume. Personally, he made use a medium low tube excited by sufficient current to enetrate the chest. There was great difficulty in select- g the proper tube, and, at the present time, it seemed o be necessary to keep ten or more tubes on hand having pecial individual qualities. All tubes did not work equally well when used with the same spark gap. Of course, medicinal, dietetic and other acknowledged methods of treatment of tuberculosis should be employed in addition to the light therapy. In giving the latter, it was his custom to give an exposure of ten minutes on alternate days.

Dr. CHARLES R. DICKSON of Toronto queried whether Dr. Boggs had made any use of the static machine, because he personally believed that his own results with this machine had been fairly good.

Dr. W. B. SNOW said that if the static machine were used in such a way as to obtain a sufficient volume of *x*-rays the results with it would equal in every respect those obtained with the coil. He would also take exception to the author's statement that the fluoroscope was a better index of the quality of the *x*-ray tube than the spark gap. One could take a very low vacuum tube in which there was no fluorescence whatever, and excite it so as to produce a radiance which would show a picture of the bones of the hand upon the fluoroscope in white, just as with a high vacuum tube. This showed the fallaciousness of the fluoroscopic test. He personally believed that practically the same results could be obtained from both classes of apparatus.

Dr. ROBERT REYBURN of Washington, D. C., said that as there could be no question that some of these cases were cured by the *x*-ray it became an interesting question how such an agency could cure. He had come to the conclusion that both in tuberculosis and in cancer the *x*-ray surrounded the morbid cells with an inflammatory product, thus preventing systemic infection. Moreover, the *x*-ray increased the nutrition of the part, so that when aided by proper diet and hygiene this agency was able to overcome the tubercle bacillus and produce a cure.

Dr. T. A. PEASE of Norwood, N. Y., spoke of a case of extensive tuberculous involvement of the glands of the neck that he had cured by static electricity.

Dr. FRANCIS B. BISHOP thought the essayist was, in the main, correct in the statement that the coil as a rule yielded better results. To obtain as good results with the static machine as with the coil the machine must be run at a very high speed, the machine itself must be very powerful and a high vacuum tube must be employed. However, for superficial growths the static machine gave as good, if not better, results because there was less liability of burning the patient and less liability of breaking the tubes. One could not get the same volume of current through the tubes with the static machine as with the coil. He had usually obtained better results from the Toepler than from the Holtz machine. The treatment of tuberculosis by the *x*-ray opened up a promising field for research. He was satisfied that he had just succeeded in curing three cases of tuberculosis by means of a convective discharge from "a cage" directed upon the shoulders and chest. No less an authority than Dr. E. L. Trudeau was authority for the statement that the left apex of the lung, in one of these patients, which had been the seat of an active tuberculous process at the time of coming under treatment, had healed. Although he was ignorant of the method by which the *x*-ray accomplished these cures, he could not accept Dr. Reyburn's theory, because if these cases were exposed too long at first to the *x*-ray there was great danger of producing a general systemic infection, thus disprovng the theory of the formation of a protecting wall.

Dr. A. D. ROCKWELL thought that if vario-vacuum tubes were employed it would be found to be immaterial whether a static machine or a coil was used.

Dr. GEORGE Z. GOODELL of Salem, Mass., remarked that he had been treating tuberculous cervical lymph nodes for the past three months in a young girl of tuberculous family history, employing a tube excited by a Kinraide coil and a spark gap of three inches, but had observed no diminution in the size of the affected nodes.

Dr. Willis P. Spring of Minneapolis inferred from the superiority of the coil in connection with *x*-ray photography that it was better than the static machine in ordinary therapeutic work, and instanced a case of suspected fracture of a metacarpal bone in which the radiograph made with the aid of the static machine hardly showed any metacarpal bone, whereas the radiograph taken with the help of the coil, under precisely the same conditions as to exposure and development, showed the metacarpal bone very distinctly.

Dr. Boggs, in closing, said that he had not intended any one to infer from his statements that he believed it was impossible to do good work with the static machine in connection with the use of *x*-ray treatment, but only that with the static machine the treatment was far more difficult than with the coil and the dosage was more uncertain. In many of his cases the distressing cough had been quickly relieved for a period of several hours by the light treatment.

**Currents of High Frequency, Apparatus and Therapeutic Uses.**—Dr. Francis G. DuBose of Selma, Ala., sent a paper with this title, which, in his absence, was read by Dr. Massey. He described at length an apparatus used abroad, by which a current of unusually high frequency —several million oscillations per second—was obtained. The nerves were unable to convey the sensations produced by such rapid vibrations, and consequently a current of over 400 milliamperes could be passed without causing pain. The current from this apparatus had been found of very general therapeutic utility, and especially valuable in obstinate cases of chronic rheumatism and of joint enlargement. As a tonic in various depraved conditions it acted more rapidly than did drugs. Post-operative pelvic pain and various congestive conditions of the pelvis were very amenable to this current. In minor surgery it would, in most cases, replace cocaine or the infiltration method for the production of local anæsthesia. The writer has made use of this apparatus for over a year, and was of the opinion that it was the most useful of all electrotherapeutic apparatus. Some difficulty had been experienced in adapting this foreign apparatus to the commercial currents employed in this country.

Dr. A. D. Rockwell took exception to the author's statement regarding the amperage or magnitude of these currents, being of the opinion that in the step-up process magnitude was lost. The current described was probably not more than 3 or 5 milliamperes. He had had some experience with the high frequency or D'Arsonval current, and had come to the conclusion that there was no effect on the general nutrition from the hypostatic current, and that almost its only use was in the treatment of superficial diseases of the skin.

Dr. Francis B. Bishop said that a few weeks ago he had seen, in Dr. H. G. Piffard's office, a 16-candle power lamp brought to full incandescence through a D'Arsonval coil. He had used the high-frequency current with good effect in the treatment of enlarged joints in rheumatoid arthritis, and also in various forms of neuritis, and believed it was going to be more generally used than any other current in electrotherapeutics.

**Electricity in the Treatment of Chronic Deafness.**—Dr. George Z. Goodell of Salem, Mass., read this paper, which was based upon replies to a circular letter and on a study of the literature rather than upon any extensive personal experience with this method. The cases treated were non-suppurative; they were examples of chronic catarrhal otitis media. Several observers had spoken of relieving the tinnitus by a mild interrupted current, but none of them reported cures. It made no difference which pole was applied to the ear. Better results were obtained from the continuous current, the positive pole being applied to the ear through the medium of sterile water in the ear. Static electricity had been but little used in this field. Electrolysis of the Eustachian tube had been quite extensively employed recently, a method of which Dr. Arthur B. Duel and the late Dr. Robert Newman were strenuous advocates. However, many aurists were of the opinion that the results were no better than from ordinary dilatation of the Eustachian tube.

**Clinical Report on the Use of the X-ray in Lesions of the Spinal Cord.**—Dr. Charles W. Daniels of Savannah, Ga., was the author of this paper, which, in his absence, was read by Dr. Snow. Two cases of tabes were reported in which very great improvement was effected, although the associated pains could not be entirely removed. This suggested the possibility of employing this method of treatment in degenerative diseases of the spinal cord in the hope of improving impaired functions and preventing a further extension of the disease process. Two cases of arthritis deformans were now under treatment, and appeared to be improving. The author disclaimed any intention of asserting that this method of treatment would effect a cure in any case of tabes, although insisting upon its probable value in controlling degenerative lesions.

**Employment of Static Electricity in the Treatment of Nervous Diseases.**—Dr. William Benham Snow of New York presented this paper. He said that the treatment of diseases of the nervous system consisted largely in the relief of inflammatory conditions and the improvement of nutrition. An electrical current for improving nutrition should have a high potential, great penetration, and a small current flow. These conditions, in his opinion, were best met by the wave current. Such an application produced contraction of muscular tissue, polarization and electrolysis. There were very few nervous diseases that were not associated more or less with inflammatory processes. In acute neuritis it was his custom to apply at first as long a spark as possible, gradually increasing it for twenty minutes; then sparks were applied to the same region along the course of the affected nerve. In chronic cases sparks were the main reliance, and should be applied chiefly to the seat of the neuritis, that is, to the region in which the sparks cause the most pain. A great triumph in electrotherapeutics was the electrical treatment of anterior poliomyelitis. Excellent results were obtained in the very early stages, a soft metal electrode being applied to the spinal cord and the wave current with an extremely long spark gap. A number of cases of neurasthenia successfully treated by the wave current were reported.

Dr. R. J. Nunn of Savannah, Ga., said that radium exhibited the highest known vibration of what we might call the ether, and it was just such vibrations that we desired for treatment. The higher the vibration the greater the curative property. He believed that all electrical currents presented vibrations, and that the lower vibrations served simply as diluents of the higher ones. The lower vibrations burned the tissues; the higher vibrations penetrated them. These papers brought out very clearly the fact that the higher vibration was the curative element, and that the better we could learn to use this agent or dilute it to suit particular cases, the better would be the result.

Dr. T. A. Pease also believed that the chief curative action of electricity depended upon vibration. With his static machine of six revolving plates and a transformer made out of watch springs in a glass tube he was able to double the usual output of the high frequency current, and could make vacuum tubes glow in any part of his office without contact with the patient.

Dr. Charles O. Files of Portland, Me., said that for many years the only explanation he had been able to give himself for the relief obtained through the agency of electricity was that it relieved congestion. Electricity, for example, hastened the circulation through the capillaries in which there was more or less stasis, and so tended to relieve insomnia. Every form of congestion seemed to be relieved by electricity, but the applications must be frequently repeated in order to secure a permanently

good result. This theory certainly formed a good working hypothesis, and, in his opinion, was in accordance with the observed facts.

Dr. J. R. STUART of Minneapolis also spoke briefly of the great power of the high-frequency current to relieve pain and reduce congestion.

**A Year's Work in Electrotherapy.**—Dr. LAURA VIOLA JUSTIN-MACKIE of Attleboro, Mass., presented this paper, based upon a clinical experience with 125 cases. Many of these had been referred to her as a last resort after general practitioners had become wearied with their futile efforts to bring about some improvement. Young, anæmic women suffering from ovarian pain, leucorrhœa and other conditions arising from local pelvic disturbance, in whom pelvic examination was undesirable, could often be relieved by electrical treatment. In the treatment of uterine fibroids she had not made use of the very high currents. She had observed very little benefit in the treatment of arthritis deformans.

Dr. MARCUS M. JOHNSON of Hartford said that, like the author, his experience had been almost uniformly favorable with regard to the relief afforded by static electricity in the same class of cases. Mention was made of a severe case of exophthalmic goiter which had been rapidly and successfully treated in this way, that is, as regards the nervous symptoms.

**Electrical Treatment of Trachoma and Corneal Opacity, with Illustrative Cases.**—Dr. MARGARET A. CLEAVES of New York presented a paper with this title. In it she detailed the history of a very severe and long standing case of trachoma. She made thirty-seven electrical applications during three months and a half, using a zinc electrode and 2½ milliamperes of current for two minutes, with an indifferent electrode, 11 square inches in area, placed at the nape of the neck. There was a steady gain. In ten days it was noticed that nearly all of the sago bodies had disappeared and the circulation had been materially improved. About six weeks after coming under care the patient could count fingers, whereas at the beginning he had been utterly unable to do this. The applications were made three times a week, which was oftener than she was accustomed to give such applications in the other cavities of the body. This was because of the partial neutralizing action of the tears. The patient completely recovered from his trachoma. He was discharged in June, 1896, and on October 13 of the same year there was no sign of the trachoma, a fact which was substantiated by Dr. William Oliver Moore. An attempt was then made to treat the corneal opacity by cathodal electrolysis, using one milliampere for from one to three minutes, three times a week. This was always followed by the mechanical action of the induced current. In six months he had recovered fully two-thirds. The boy had originally been an object of charity, and the treatment had made him a useful member of the community and had prevented him from becoming a public charge.

**The Successful Treatment of Eighteen Cases of Granular Lids by the X-ray and High Frequency Vacuum Electrodes.**—Dr. ALBERT C. GEYSER of New York read this paper. The *x*-ray was used for the specific purpose of checking the granular hypertrophy. In carrying out this method the tube must not be brought nearer than 6 or 8 inches. Exposures of from three to five minutes were given on alternate days for two or three weeks, and then the high-frequency current was employed to improve nutrition. The eyelids were everted by attaching a strip of adhesive plaster and a weight, and placing a lead pencil underneath the lid to facilitate the eversion. The surrounding parts were protected by a shield.

*Wednesday, September 23—Second Day.*

**Exophthalmic Goiter and Its Rational Treatment.**—Dr. FRANCIS B. BISHOP of Washington, D. C., read this paper. The author took the ground that Graves' disease was superinduced by the early and continued use of the corset, and that anæmia, through faulty metabolism, often acted as a predisposing cause. In the management of such cases rest was an important factor. These persons should go to bed early and get up late. All pressure should be removed from the chest and abdomen, and deep breathing exercises should be enjoined. As to the diet, nitrogenous food was of the first importance, and although they would not gain flesh on this diet, the nutrition of the muscular and nervous systems would be materially improved. After years of medication the conclusion had been forced upon him that it was of little use. Owing to the low resisting power of these patients they should not be subjected to anæsthesia or operation unnecessarily. Many authorities agreed that the best results from treatment in this disease had been obtained by the proper employment of electricity. We knew that the vagus was easily stimulated in the neck, and that this could be done much more easily than stimulation of the sympathetic. By the stimulation of the vagus the heart's action would be slowed and steadied. The speaker preferred to apply the continuous current, stimulating both nerves at the same time. A large sponge electrode attached to the positive pole should be placed high up on the neck, and a bifurcated cord with two sponge electrodes placed on each side of the lower part of the neck over the pneumogastric nerves and impinging upon the thyroids. A current, the strength of which was increased up to the point of toleration, should be allowed to pass for ten or fifteen minutes, or until a decidedly quieting effect was produced, and then the current should be applied directly to the gland for about the same length of time. The applications should be made on alternate days. Recent experience in the treatment of these cases by the high frequency current had yielded very satisfactory results. He was convinced that much good came from what Dr. Rockwell called "circulatory drainage." The current strength was regulated in these cases by the effect upon the pulse.

Dr. G. BETTON MASSEY spoke of the recently published views of Sajous concerning the functions of the thyroid and their relation to the functions of the adrenals and the pituitary bodies.

Dr. T. A. PEASE of Norwood, N. Y., said that during the past two years he had developed a method of treating exophthalmic goiter which he could recommend. A 4-per-cent. solution of adrenalin was applied to the gland by means of a copper disk electrode, and the continuous current was passed until the skin was thoroughly blanched. The high frequency current was then applied through a modification of Dr. Snow's wooden electrode. This gave better results than any other method of treating exophthalmic goiter.

Dr. A. D. ROCKWELL believed that treatment of this disease by the galvanic current was superior to all other methods. About a dozen years ago he had published an analysis of about forty cases of exophthalmic goiter, twelve of which had been cured. Since that time almost every case had shown improvement, and a large number had been cured, largely as a result of the thoroughness of the treatment. He made use of a very moist and pliable clay electrode, 2 or 3 inches in diameter, applied over the ciliospinal center, and an electrode, 4 or 5 inches in diameter, over the solar plexus. With electrodes of this size and material his advice was not to be afraid of using too much current strength; with the arrangement just described he frequently employed a current of 75 milliamperes.

Dr. W. W. EATON of Danvers, Mass., said that he could confirm what Dr. Rockwell had said concerning the great efficacy of galvanic treatment in these cases, as he could recall only one case in ten years that had not been symptomatically cured along with the disappearance of the enlargement of the gland. He molded a clay electrode to the growth, and employed at least a current of 30 or 40 milliamperes, often very much more.

Dr. BISHOP, in closing, said that he, too, had found the

continuous current of the greatest benefit, but recently he had done still better with the high-frequency current as an auxiliary. He never used clay electrodes, preferring those made of sponge and having a tin foil backing. The electrode on the back should not be so large as to divert too much of the current from the thyroid. The patient should be in the reclining position, and the current should be very gradually increased, watching the effect on the pulse. He had occasionally used currents of 50 or 60 milliamperes, but had not found that such strong ones were often desirable.

**Effect of the X-ray upon the Eyesight.**—Dr. WILLIS P. SPRING of Minneapolis asked for experience regarding the effect of using the fluoroscope on the eyesight of the operator.

Dr. W. J. HERDMAN of Ann Arbor remarked that Mr. Rollins of Boston declared that there was a uniform deterioration of the eyesight from the use of the *x*-ray.

Dr. C. R. DICKSON of Toronto remarked that one of the absent members of the association had had his eyesight almost ruined in this way.

Dr. LORING of Boston said that a very simple means of protecting the eyes was to attach a thick piece of glass behind the fluoroscopic screen. He could recommend this from personal experience.

Dr. R. J. NUNN advised that the glass used as such protection should in all cases be tested to determine if it were really opaque to the *x*-ray.

**Zinc-mercuric Cataphoresis of Tuberculous Glands.**—Dr. G. BETTON MASSEY of Philadelphia gave a practical demonstration of this method. A sliver of zinc, sharpened at one end, is used for the active electrode. If the gland to be treated is unopened, the sliver of zinc should be uninsulated at first, and should not be dipped into the mercury until just before use, otherwise it would become too brittle. The point of introduction is chilled with an ethyl chloride spray and the puncture is made with a Hagedorn needle. Immediately afterward the zinc electrode should be inserted, and then a current of ½ to 3 milliamperes used for half an hour. A drop of a saturated solution of cocaine may be dropped in along side of the electrode. A cylinder of necrosed tissue comes away within a few days, and the treatment is repeated through this opening, using now an insulated zinc electrode, *i. e.* another sliver of zinc prepared as before. The gland becomes so impregnated with mercury that it drains downward and favorably affects other glands in the chain. The active agency in the treatment is the chloride of mercury and zinc. In addition to this, Dr. Massey said there was a marked general improvement in these patients, although no other method of treatment was employed at the time. He had used the method in six cases. A little girl was shown who had been treated for about three months, three times a week.

Dr. ROBERT REYBURN spoke against the use of the knife in these cases, as in cases of malignant disease, on the ground that surgical operation laid open so many channels for absorption and further infection.

Dr. M. A. CLEAVES said that about five years ago she had successfully treated one case of tubercular adenitis by the same method, using, however, copper instead of zinc as the electrode.

**A Plea for Electrotherapeutics Proper.**—Dr. WILLIAM J. HERDMAN of Ann Arbor, Mich., presented under this caption a thoughtful paper in which he decried what he called the recent tendency of the association to run after fads and fancies and "sell its birthright for a mess of pottage." He deprecated the disposition of the members to forsake the true electrical modalities, to foster whose special used the association had been organized, and to spend much time and energy in border-line studies. The author then reviewed in a simple and forceful manner the evidence showing the manifold and important therapeutic properties of these modalities. He declared that the therapeutic actions of the constant current, about which too little was heard in these latter days, was alone worth more than half of the drugs listed in the pharmacopœia or the instruments employed by the surgeon. As a case in point the speaker referred to an osteosarcoma of the jaw which he had successfully treated by electrolysis, making six applications at intervals of a week. The patient had practically no suffering, he lost no time from business, there was no impairment of deglutition or loss of symmetry of the face. This was but one of several similar cases, the evidence regarding which was in his possession, and he, therefore, asked his hearers whether they could honestly say that there was any other method that could accomplish so much.

Dr. MARCUS M. JOHNSON said that as he was a surgeon he could thoroughly appreciate the remarkable success of Dr. Herdman in the reported case of osteosarcoma of the jaw. Although it could not be said that the disease would not recur, it was a fact that the patient had not been subjected to torment nor his life jeopardized in the attempt to eradicate the disease. While surgery was doing a great work in many lines, yet in certain directions it had its limitations, and this was one of them. He therefore welcomed all the aid that could be derived from electricity.

Dr. F. B. BISHOP said that at the Buffalo meeting almost every one was speaking of the static current, and the old constant or direct current seemed to be almost forgotten. He thought there was a slight difference between the static current and the high-frequency current, especially in the use of the spark. The spark of the high-frequency current was very much more penetrating and was, at the same time, less painful.

Dr. W. B. SNOW said that the members were physicians, first, rather than electrotherapeutists, and it should be their earnest wish to do the best possible for their patients. They should, therefore, be able not only to use electricity, but any other physical agent, *e. g.* other forms of vibration, such as heat and light.

**Radiant Light Baths in the Treatment of Neuroses.**—Dr. THOMAS D. CROTHERS of Hartford read this paper. The author stated that another year's experience with this method had led him to think even more highly of it than in his former paper, and the patients who took both the Turkish bath and the radiant light bath uniformly preferred the latter, because of the great exhilaration during the bath, and the greater feeling of restfulness afterward. Observations on the pulse and temperature also seemed to point to the superiority of the light bath. The marked sudorific action of these baths resulted in a free elimination of toxins, and appeared to be largely instrumental in restoring the patients to health. The radiant light, penetrating the deeper tissues of the body, was thought to be turned into heat, thus achieving greater therapeutic results than the ordinary hot-air bath.

Dr. M. A. CLEAVES said that for the past ten years she had been interested in this subject, but her experience had been chiefly with the arc light. She thought the incandescent light bath was better for the special class of cases considered in the paper.

**A Case of Asthma with Fibroids and Pelvic Adhesions Cured by Galvanism.**—Dr. CHARLES A. COVELL of Syracuse reported this case. The asthma was of reflex origin, and ceased as the pelvic condition was relieved. The patient was cured by the electrical treatment, although a well-known gynecologist had declared that she could not be relieved except by the removal of the diseased pelvic organs.

Dr. GUSTIN-MACKIE remarked that at one time when treating the uterus for the control of hemorrhages arising from the presence of a small interestitial fibroid, she was surprised to find the patient's asthma relieved coincidentally with the pelvic condition.

**The Use of the X-ray in the Treatment of Malignant Growths.**—Dr. MARCUS M. JOHNSON of Hartford reported

this paper cases to illustrate the superiority of this method in certain cases over surgical operation.

**Radium, with a Preliminary Note as to Its Therapeutic Uses in Cancer.**—Dr. MARGARET A. CLEAVES of New York read this paper, which will appear in an early issue of the MEDICAL RECORD.

**The Present Status of X-ray Therapy in the Management of Cancer.**—Dr. CLARENCE E. SKINNER of New Haven read this paper. He said that it was impossible to formulate a positive verdict regarding *x*-ray therapy because of the careless and unskilful methods that had been employed by many who had reported cases treated by this agency. However, the *x*-ray might be said to be one of the best, if not the best, means at present at our command for the treatment of malignant disease, because a large a proportion of cures had been obtained by this method as by any other, and a smaller proportion of recurrences had been noted within a given period. Moreover, the majority of the recurrences had yielded readily to another application of the *x*-ray. In the early stages it was now thought best, when practicable, to resort to thorough removal by surgical operation, following this by a thorough course of treatment by the *x*-ray. There was almost unanimous agreement as to the advisability of using the *x*-ray following all operations for cancer in order to prevent recurrence and to relieve pain. He knew of but one operator who claimed to have effected a cure in cancer of bone by means of the *x*-ray. As to whether *x*-ray hastened metastasis was still *sub judice*, yet the evidence seemed to favor the view that it did not have such action. His personal belief was that there was a therapeutic difference between the action of the *x*-ray as obtained from the coil and from the static machine. The general opinion now was that tubes giving soft rays of high penetration were best for the treatment of deep growths, and that tubes of either high or low penetration might be used for superficial growths. There was now some evidence to show that a person who had been constantly exposed to the *x*-ray for a long time was liable to develop cancer of the superficial tissues. The notion that a person who had been tanned by the *x*-ray could not be burned must undergo revision, for he had recently had a case showing the falsity of this view.

**The Rontgen Ray as an Aid in Diagnosis.**—Dr. HERMAN GRAD of New York made a plea in this paper for a systematic and extensive use of the Röntgen ray for the detection of gross pathological changes, just as the microscope was now depended upon for the detection of minute changes of this kind. Both the positive and negative value of the Röntgen ray in fracture were emphasized by the report of illustrative cases and the presentations of radiographs of the same. Some of the uses of the *x*-ray in general medicine were also dwelt upon.

**The Use of Galvanic Electricity in the Treatment of Cancer and Kindred Diseases.**—Dr. WILLIAM WINSLOW EATON of Danvers, Mass., read this paper. In the earlier cases reported in the paper the continuous current was used from a forty-cell battery. The strength of the current used varied up to 75 milliamperes ordinarily, the application lasting for fifteen minutes and the full strength being attained in two or three minutes. A number of cases were reported, some of them of a most desperate character, in which treatment by the galvanic current had resulted in marked improvement, and, in some instances, had kept the patient in comparative health and usefulness for a period of several years. Of the eight cases reported, one was living at the end of one year, one at four years, one at six and two at seven years after the treatment. These cases of internal cancer were advanced and inoperable. The author was of the opinion that this potent but harmless agent, the continuous current, should be used in every case of cancer, and should be reinforced, if necessary, by the use of the *x*-ray.

Dr. G. BETTON MASSEY said he was convinced that in some cases of supposed cancer of the breast the use of the simple galvanic current had been followed by an increase of the growth, due, no doubt, to the increased nutrition of the part. He thought some of the cases reported might have yielded still better results, and without incurring undue risk, by the employment of mercuric cataphoresis.

Dr. A. D. ROCKWELL said that while he had been interested in the cases just reported, his own discouraging experience with the galvanic current in the treatment of cancer twenty-five years ago led him to feel that this question must still be considered as *sub judice*. It was probable that the good results secured by Dr. Eaton were largely attributable to the use of the *x*-ray.

Dr. ROBERT REYBURN expressed his belief that cancer was not a germ disease, but rather of the nature of a retrograde metamorphosis. The recently published views of Dr. Robert Bell of Glasgow gave color to the view that many factors, which caused deterioration of the general health, might enter into the etiology of cancer, and made it probable that the successful treatment of cancer in the future would embody careful and rational medical treatment.

Dr. Eaton, in closing the discussion, said that most of his cases had been treated before mercuric cataphoresis for cancer was known, and that it was only in the past two years that he had made proper use of the *x*-ray. In external cancer he had found the *x*-ray very efficacious, but apparently of little avail in deeply situated cancers. He was of the opinion that with the galvanic current there was a certain chemical dissolving effect that was not obtainable with the electrical modalities.

*Thursday, September 24—Third Day.*

**Report of the Committee on Current Classification and Nomenclature.**—Mr. WILLIAM J. JENKS, E.E., chairman of the committee, presented an exhaustive and highly instructive report. He said that the term "galvanic current" should never be used, and that, so far as possible, the term "constant current" should take its place. The faradic current should always be referred to as an induced current, or better still, as the magnetic induced current. The preliminary report presented by the committee one year ago had been sent to many electrical engineers, inviting their criticism, but up to the present time practically no criticisms had been received, thus indicating that the suggestions of the committee regarding nomenclature had met with very general approval. The speaker then exhibited a number of diagrams representing the combinations of primary static generators and secondary or modifying apparatus used by physicians. He said that it was evident that intelligent classification of these must be based primarily upon the curves which properly represented the resulting currents. The report here gave at length the observations and conclusions of Prof. Samuel Sheldon of the Brooklyn Polytechnic Institute. This observer, working with the well-known make of static machine, found that when this machine was running at 315 revolutions per minute without excitation it consumed 106 watts, and that the loss due to friction was 30 watts, or $\frac{1}{25}$ of a horse-power. After exciting the machine, the total power consumed was 184 watts, or about $\frac{1}{4}$ of a horse power. It had been found, to the surprise of the committee, that the machine, under certain conditions, would deliver 27 per cent. of the energy put into it by the motor. If the machine were operated with its discharging rods in contact the current should be directly proportional to the speed. While the discharging rods were in contact there was very little difference of potential in the parts of the machine situated between the collecting cones. The report then described three different kinds of currents obtained from these machines, viz., (1) The current taken from the discharging rods, the latter being separated; (2) the current taken from the outer coating of Leyden jars whose inner coatings were

connected with the separated discharging rods, and (3) the current taken from a coil of wire connected with the outer coatings of the Leyden jars whose inner coatings were connected with the separated discharging rods. Mr. Jenks then went on to say that a condenser of large capacity would tend to produce relatively slow oscillations. The electrical engineer could determine in advance with mathematical accuracy the result that would be obtained by the introduction of such modifying devices, but when living human tissue was interposed an absolutely unknown factor was introduced as regards its effect upon the rest of the circuit. No accurate measurements, so far as known, had yet been made with regard to the effect of the human body on currents of alternating character and high pressure. This physically active section of the external circuit must, therefore, be investigated before one could determine the curves of the currents employed. Dr. Kellogg had made a series of experiments on the curves of the currents employed by physicians, but apparently without the patient in the external circuit. The various currents employed in therapeutics were then described in detail with the aid of diagrams.

**A Plea for an Accurate and Scientific Method of Röntgen Ray Treatment.**—Dr. MIHRAN K. KASSABIAN of Philadelphia presented this paper. He exhibited a ruled blank record with headings intended to provide for accurate notes concerning the history of the patient, the kind of apparatus and technique employed, and for the diagnosis. It was advised that photographs should be taken just before and immediately after treatment on isochromatic plates, and, if possible, life size. Instruments for measuring the interruptions and the power of individual *x*-ray tubes were described and criticised. The author insisted that the effect upon the patient was not dependent upon the length of the exposure, but upon the number of interruptions and the extent to which the tissues were penetrated. One great difficulty encountered in practice could be eliminated by employing self-regulating tubes. It was recommended that a voltmeter and an ammeter be introduced where the current goes into the primary, and so determine approximately the intensity of the rays, because other methods of measurement were dangerous either to the hands or eyes of the operator.

Mr. R. G. BROWN, E.E., remarked that he could not see that any reliable measurements could be made with the meters placed as described, and in this opinion Dr. Boggs concurred.

**Perineuritis.**—Dr. A. W. BAER of Chicago read a paper with this title. The author called attention to the fact that one of the best means of differentiating between facial neuralgia, due to suppuration at the root of a tooth, and a neuritis was by the application of electricity. When there was abscess formation the patient almost invariably complained of increased discomfort when electricity was applied. The static treatment was the easiest, but it was not so beneficial as the continuous current. Several cases were reported.

Dr. A. Z. GOODELL of Salem, Mass., reported a case of severe neuritis and writer's cramp that had yielded most satisfactorily and promptly to the high frequency derived from the Kinraide coil.

**The Electrothermal Bath.**—Dr. CHARLES H. SHEPARD of Brooklyn recommended in this paper the conjoined use of the hot-air bath and of electricity as a means of improving nutrition. .

Dr. W. J. HERDMAN thought it very encouraging that a hydrotherapeutist should take such a broad view of the subject. The use of the induced current afforded an admirable stimulant and corrective for the debility consequent upon the use of the bath as an eliminant.

**Death of Dr. Robert Newman.**—Suitable resolutions on the death of Dr. Newman were adopted, and a committee was appointed to collect his writings into one volume.

**Officers Elected.**—*President*, Dr. A. D. Rockwell of New York; *First Vice-President*, Dr. Willis P. Spring of Minneapolis; *Second Vice-President*, Dr. William Winslow Eaton of Danvers, Mass.; *Treasurer*, Dr. Richard J. Nunn of Savannah, Ga.; *Secretary*, Dr. Clarence Edward Skinner of New Haven. *Executive Committee*, Dr. Francis B. Bishop of Washington, D. C.; Dr. Daniel R. Brower of Chicago, and Dr. Maurice F. Pilgrim of New York.

**Next Meeting.**—The next annual meeting will be held in St. Louis on September 13, 14, and 15, 1904.

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-third Annual Meeting, Held at York, September 22, 23, and 24, 1903.*

**Special Report to the Medical Record.**

*Tuesday, September 22—First Day.*

THE meeting was called to order at 9.30 A.M. by the President, Dr. William M. Welch of Philadelphia, and was opened with prayer by the Rev. E. T. Jeffers, of York after which addresses of welcome were delivered by Hon. M. B. Gibson, Mayor of York, and Dr. N. C. Wallace, President of the York County Medical Society.

**The Address in Surgery** was delivered by Dr. WILLIAM L. ESTES of South Bethlehem, in which the author discussed the prognosis of surgical cases, believing the most important elements to be heredity, environment, and habits and physical condition.

**The Address in Hygiene and State Medicine** was delivered by Dr. SENECA EGBERT of Philadelphia. He called attention to the fact that in 1900 the population of those districts of the United States in which a system of mortality registration had been organized was 28,807,260, as compared with 19,659,440 in 1890: the death rate during the intervening decade having decreased from 19.6 to 17.8 per 1,000, which would mean the saving of 51,853 lives in the registration area annually. He demonstrated the value of the purification of the water supply, installation of better systems of sewage-removal and disposal, supervision of milk and food, improved quarantine regulations, improved street pavings, development of parks, etc., by giving statistics showing the mortality rate in different cities before and after the introduction of these factors. He remarked particularly the value of preventive measures for the avoidance of smallpox, pneumonia, diphtheria, scarlet fever, typhoid fever, malaria, and believed that in order to secure the best results the co-operation of the general public should be secured, which could best be done by as free a dissemination of knowledge on sanitary subjects as possible.

**The Address in Neurology** was delivered by Dr. CHARLES B. MAYBERRY. He argued for better results in the treatment of the insane, which he believed could be obtained by (1) More extensive instruction psychiatry, both didactic and clinical, in the courses of our medical schools; (2) The construction of small psychopathic hospitals for the separate treatment of the acute curable insane; (3) The organization of a system of out-patient departments, by which the discharged patients may be kept under observation for one year after leaving the institution; (4) The creation of a central laboratory for the investigation of pathological conditions underlying mental disease.

**The Practical Treatment of Pulmonary Tuberculosis** was the subject of the Address in Medicine, which was delivered by Dr. H. M. NEALE of Upper Lehigh. He said he believed that improved nutrition of the patient by forced feeding, not however to such an extent to overburden the stomach, was one of the most important factors in the treatment of consumption. This should be in conjunction with fresh air, sunlight, rest, and cleanliness. He did not believe high altitude was essential to the cure of consumption, and, in fact, felt that it was detrimental, if the patient purposed returning to his home later, for the dilatation of the air vesicles induced by the prolonged

sidence in the high altitudes was a positive disadantage.

**The Medical Expert Witness.**—Dr. G. W. WAGONER of ohnstown read this paper He emphasized the importance f having men of the highest character and ability to act i this capacity. For the accomplishment of this result e believed the following suggestions would be of value: ;) Make the expert witness a State witness to be paid just and dignified fee by the State. (2) Have them ppointed by the Court; one at the suggestion of the rosecution, one at the suggestion of the defence, and a iird by the Court; all of them to be practitioners, of arning, skill, wide experience and honorable standing in ie profession. (3) Require these witnesses to hear the stimony, receive the contentions of the counsel, make he scientific examinations necessary, and submit a report f their conclusions to the Court. (4) The report may be xplained by any or all of the experts in response to uestions by the Court, but the experts may not be ross-examined. Their report to go to the jury with the roper legal instructions of the judge, but uncontaminated y the objections of counsel, as is his charge.

**Streptococci and Antistreptococcus Sera.**—Dr. D. H. BERRY of Philadelphia in this paper stated that the earlier lassification of streptococci into S. longus and S. brevis, as ell as the differentiation of S. pyogenes and S. erysipelatos ad been demonstrated to be erroneous, and that in the light f recent studies upon other groups of bacteria, the proession must be prepared to expect the same variations of e morphological, biological, and pathogenic characters of ultures of streptococcus derived from different sources. t the same time these variations were insufficient to arrant the separation of these different types of organms into distinct species. The studies of Michaelis and Aronson indicated that the antistreptococcus sera were ot bactericidal in their action, since streptococci grow most equally well in normal and immune serum. The nclusions reached by these two investigators were that e immune serum stimulates the activity of the phagotes, and that when this stimulation can no longer be duced the serum treatment is without avail.

**The Necessity for the More Careful Instruction of Medical udents in the Diagnosis of Preventable Diseases.**—Dr. ENJAMIN LEE of Philadelphia, in his paper by this title, mphasized the importance of clinical observation of the arious types of contagious disease in conjunction with idactic instruction, giving especial attention to typhoid ver and smallpox. He felt that the tendency, with both udent and instructor, was to devote too much attention o therapeusis and not enough to diagnosis.

**The Effect of an Improved Municipal Water Supply upon e Prevalence of Enteric Diseases.**—Dr. J. FRANK SMALL f York in this paper suggested that the water supply in ork, as supplied by a private corporation, The York ater Company, be compared with that furnished in other d larger cities. A table was presented showing the typhoid rve before and since the installation of the filtration stem, which demonstrates that the rate per thousand s regularly diminished. In conclusion is given the reults of bacteriological examinations of the water made at arious times. It is believed that an efficient filtration f a municipal water supply has a decided effect in lessening the prevalence of enteric disease.

**A Contribution to the Clinical Study of Cerebrospinal eningitis.**—Drs. THOMAS C. ELY and J. J. SNYDER of Philadelphia presented a paper upon this subject, which as read by Dr. Ely. The cases reported represent a eries composed of twenty-three sailors from the U. S. Training Ship *Minneapolis*, at League Island, Philadelphia, and treated at the Naval Hospital, Philadelphia. The marked irregularity of the temperature and pulse were noted and varied clinical pictures, such as the comparative constancy of Kernig's sign, the marked variability of Babinsk's sign, the "crane-like" posture of the head, being set back in rounded shoulders with chin tilted forward, and the rarity of paralysis of individual cranial nerves. There was no case of blindness, and only one of deafness. Early death in some cases was accredited to the action of specific toxins on cardiac or respiratory centers. A notable feature was the vagueness of symptoms in some instances; one patient complained of rheumatic pains, while closer examination disclosed some rigidity of the muscles of the neck, and Kernig's sign was present and other well-marked phenomena. One had symptoms and a rash like typhoid fever. Widal's reaction was negative. Pneumonia masked the symptoms in the first case and in some others, and many cases resembled influenza. Only in epidemics would these cases have been classified, and the fact led to the query whether sporadic cases were not often overlooked.

**Aneurysm of the Left Subclavian Artery Treated by Wiring and Electrolysis.**—Dr. JUDSON DALAND of Philadelphia reported this case. The patient was a man aged fifty-two years, a laborer. Two years ago he first noticed a tenderness in the left side of the neck and pain in the left shoulder and arm. Seven days later he observed a pulsating mass in the left side of the neck which gradually increased in size until, at the time of first examination, April 24, 1903, it was as large as a cannon ball. Examination of heart, lungs, liver, spleen, and urine gave negative results. The diagnosis of aneurysm was made. Twenty feet of gold wire was introduced into the sac through a hollow needle and a galvanic current gradually increasing from 1 to 80 milliamperes was employed for about 110 minutes. The pulsation and size of the tumor temporarily decreased, but afterward increased, and death occurred twenty days after operation. Necropsy showed a cocoanut-shaped aneurysm involving the left subclavian artery from its origin to the axillary artery. Its cavity was occupied in large part by a clot in varying stages of organization through which the wire was well distributed.

**Typhoid Fever.**—Dr. L. B. KLINE of Catawissa called attention to the increasing ravages of typhoid fever, of which cities of all sizes and country places furnished their due proportion. In the treatment he approved of the maintenance of the intestinal tract in an aseptic condition. Special antipyretic treatment should be given by cold sponging or cold baths when not contraindicated, and by cold water or ice to the head. Medicinally quinine might be used to reduce fever. Coal-tar products should be interdicted. The heart should be sustained by strychnide in doses of gr. $\frac{1}{30}$ to $\frac{1}{10}$ every four to six hours as indicated.

**The Dietetic Treatment of Chronic Nephritis.**—Dr. J. M. ANDERS presented this paper. He stated that the dietary that fails to meet the requirements of nutrition plus the loss of albumin is inadequate. Efforts to lessen the degree of albuminuria at the expense of the quality of the blood and general nutrition are not so much blessings as evils. By means of a proper diet it is possible to postpone, if not at times prevent, the later development of true contracted kidney. It is not possible to formulate a dietary suitable to all individual cases. Indications also vary with the stage of the morbid process. In his experience the long continued restriction of the diet to milk alone produced an undue general weakness. In advanced cases of granular kidney active heart disease is a constant concomitant and the integrity of the cardiovascular system must be preserved. He expressed the view that clinicians manifest a general tendency to supply the system with an insufficient amount of albuminous aliment, in view of the constant systemic drain, and pointed out that the proteids form the essential basis of all tissues, and that perfect metabolism cannot be accomplished without a certain definite quantity of nitrogen. He is of the opinion that red meats show as good nitrogen-excretion as white meats. Fats are allowable, and butter, except in cases of obesity. Whole milk should be a con-

siderable portion of the diet, meats should be somewhat restricted, while fruits and green vegetables and rice may be given rather freely. He emphasized the fact that the normal physiological quantity of food is required, which is practically: 110 to 130 grams of albumen, 350 to 400 grams carbohydrates, 75 to 110 grams of fat, 2,500 to 3,000 grams of water, and 18 to 30 grams of inorganic salts. The extent to which the given diet contributes to the nutrition and development of bodily strength must be carefully estimated. This is accomplished by noting the effect upon the degree of albuminuria and also upon the kidney elimination of the normal metabolic products. The importance of carefully recording the bodily weight of the patient was emphasized.

Dr. THOMAS D. DAVIS of Pittsburg advised giving milk to these patients in a cup instead of in a tumbler; they could not see what was coming and therefore their minds were not prejudiced against it. The addition of a bit of ice and some vanilla was an advantage.

**Recovery from Perforations in Typhoid Fever.**—Dr. JOHN H. MUSSER of Philadelphia in this paper reported a case of typhoid fever seen in a relapse. In the primary attack the patient had pleuropneumonia, on account of which he was extremely prostrated. The temperature was normal on the 29th and 30th of May. On the 31st it began to rise gradually. By the 5th it was 104° in the evening. On the morning of the 4th, after a slight chill, it fell to 102°. The pulse rose to 130 and there was slight abdominal tension. Frequent micturition was marked; pain occurring as soon as there was small accumulation of urine in the bladder. Dr. Musser saw the patient with Dr. Mueller. The patient was in moderate collapse and the abdomen was distended. There was no rigidity. Pain was complained of at a point half way between the pubis and the umbilicus. The absence of rigidity suggested appendicitis, especially as the bladder symptoms had not abated. The vermiform dipped into the pelvis. Rectal examination showed slight tenderness in the pelvis but no undue fulness. Vomiting took place four or five times during the day. Notwithstanding the indefinite nature of the symptoms it was believed that perforation had taken place. The patient was so desperately ill and had been so very ill from the previous penumonia, resolution not having fully taken place as yet, that it was deemed unwise to interfere. On the following days the temperature remained between 103° and 104°; pulse 120 to 130. On the 9th day the temperature fell to 99°; pulse to 106; respirations to 18. On the morning of the 10th day the temperature was again 104.5° and continued at this point through the day. In the evening it had fallen to 101°. Blood was found in the stools. Repeated discharge of blood throughout the remainder of the night and all the following day showed that a continued hemorrhage was in progress. Death occurred on the 11th day from exhaustion. At the autopsy a small ulcer in the ileum was found to have perforated the bowel and formed adhesions to the bladder. There was very decided localized peritonitis, but no extension to the general peritoneum.

*Wednesday, September 23—Second Day.*

**X-ray, Light, and High-frequency Electricity.**—Dr. RUSSELL H. BOGGS of Pittsburg sent a paper with this title in which he directed attention to the three distinct rays composing sunlight or white light, *i. e.* the caloric, luminous, and the actinic or chemical rays, which may be filtered from the compound rays by the employment of colored glass or other media. He emphasized the value of individual attention to each case, and the necessity of adapting the treatment to each particular case. He stated that the effects produced upon pulmonary tuberculosis had demonstrated that the value was not confined alone to superficial conditions. He reviewed the process of inflammation which takes place and mentioned the value of the *x*-ray applied to the surface painted with iodine for rheumatism, as it will force it into the tissues. In lupus, epithelioma, and carcinoma, he believed the *x*-ray to be of great value. He remarked the value of the *x*-ray also in rheumatism, rheumatoid arthritis, neuralgia, and tuberculosis of various parts of the body.

**The X-ray Treatment of Chronic and Malignant Diseases of the Skin and Superficial Tissues** was read by Dr. SAMUEL H. HELLER of Lancaster, in which he reported the following results: Carcinoma responded quickly in all cases, pain being entirely absent in a few days and contraction beginning at once. In six cases a permanent cure was effected. In epithelioma some cases had responded, others showed no improvement or reacted very slowly. In lupus erythematosus, he had four cases, all of which were cured. In tuberculous lupus his results were equally as good, the scales coming off in successive drops until a clean smooth surface was left with scarcely any scarring. A case of fissure eczema involving the palmar surface of both hands was much benefited. In cases of ivy poisoning, acne, and papilloma, good results were obtained.

**Röntgen Rays as a Palliative in the Treatment of Cancer**—Dr. CHARLES LESTER LEONARD of Philadelphia read a paper dealing with the prophylactic and palliative value of the Röntgen rays in cancer. He said that the Röntgen rays were the most valuable and active agents that had ever been found for the treatment of cancer, but the permanence of the cures had not been established, and he believed that every case of cancer, with but few exceptions, should be operated upon at as early a period as possible to remove the great mass of disease, and then treated by the Röntgen rays to destroy the small masses that might have escaped the surgeon. This would give the patient the benefit of the two best methods known. In many hopeless cases in which operation was impossible the Röntgen rays had produced apparent cures. In others they had restored partial health, while in all they had been of benefit, relieving much of the distress and suffering that accompany the final stages of the disease.

**Röntgen Rays in Therapeutics.**—Dr. MIHRAN K. KASSABIAN of Philadelphia considered at length the conditions amenable to this method of treatment. He contrasted the treatment of carcinoma by the *x*-ray with operation, and believed the growth should be removed, if possible. The superficial growths were more easily reached than the deep-seated ones, and the production of dermatitis is due to faulty technique.

**Some Problems in Surgery.**—Dr. GEORGE D. NUTT of Williamsport read a paper with this title in which he stated that a thorough practical knowledge of the practice of medicine, and diagnostic ability, as well as skill in the use of the knife, were essential in surgery, and the surgeon should possess the highest ideals of integrity and professional honor. He felt that more care should be used in operative technique, so as to leave less postoperative deformity, discomfort, and dangerous sequences; and particularly is this true in small operations, especially on exposed parts of the body. In the surgery of the hands and fingers the utmost care should be taken to leave as little deformity as possible and to save every portion that may be of use to the patient. By the improved means of examination and treatment better results and less deformity should be obtained in cases of fracture. He urged that in all abdominal work which is not included under the term, emergency surgery, we should not lose sight of nature's forces and her ability to overcome and eradicate disease, nor the neurotic element which enters into so many cases that seek surgical advice; and that the patient should never be submitted to an exploratory operation until every other means of diagnosis has failed to reveal the true state of the case.

**Proctocolitis, with Special Reference to Treatment** was the title of a paper read by Dr. WILLIAM M. BEACH of Pittsburg, in which he stated that (1) proctocolitis is a

disease that attacks old and young—in the experience of the author occurring more frequently in the male sex. (2) The essential symptoms are pain, constipation, and membranes. (3) In diagnosis, appendicitis, malignant and pelvic diseases are to be eliminated. (4) Reflex symptoms must be recognized when they occur, as neuralgia, anæmia, vertigo, dyspepsia, cardiac irritation, asthma, and neurasthenia. (5) The history of acute dysentery of bacillary origin and the neuroarthritic diathesis must be reckoned as causal factors. (6) Ptosis of the abdominal viscera, appendicitis and tumors may be complications in severe cases. (7) The diet should consist for the most part of soft foods, eliminating green vegetables, fruit, nuts, and alcohol. Milk is the standard aliment. (8) Certain medicines, such as castor oil, to secure normal action of the bowels; tincture of nux vomica in doses of two drops every three hours for anorexia; antitoxins, such as salol, bismuth salicylate, soda salicylate, and guaiacol carbonate, to relieve the reflex symptoms of autointoxication, and dilute nitric acid in ten to fifteen-drop doses for the relief of hyperchlorhydria, are of use when indicated, but should be selected and used with great care. (9) With the above regimen the most efficient procedure is to wash out the colon.

**Modern Treatment of Fractures.**—Dr. H. S. McCONNEL of New Brighton read this paper. Fractures, he said, were imperfectly treated owing to faulty teaching of anatomy and surgery in the schools, the subject not being presented so the student associated structure with function. An attempt should be made in every case of compound fracture to convert it into a simple. Tight bandaging was harmful. Splints snugly secured were to control muscular action rather than to make direct pressure upon the fragments. In fractures of lower end of the humerus, involving the joint, the extended position enabled the surgeon to inspect and redress without pain, and led to complete restoration of function in shortest possible time. The proper splints for these fractures were made of absorbent cotton rolled upon itself, covered with gauze and extending from shoulder to fingers. In fractures of the leg, the fracture box should be discarded as a relic of barbarism. The permanent dressing for this injury was best made with three pieces of canton flannel twice the width desired, posterior extending from middle of thigh to malleoli, side pieces from upper border of patella to two inches below the sole; these folded upon themselves, smooth side out, and covered with from six to eight layers of a moist 3-inch plaster-paris bandage by a to-and-fro motion, lengthwise; then the uncovered portion of flannel brought over the plaster, makes them ready for use. The posterior was first applied snugly—while firm extension was made—with a few turns of wide gauze bandage; then the side splints overlapping posterior, but leaving a space anteriorly of not less than one inch exposing spine of tibia. The advantage of this method was that a light, firm dressing could be molded into all the irregularities. The use of canton flannel and overlapping of splints made it impossible to constrict the limb.

**Surgical Treatment of Recent Fracture of the Patella.**—Dr. EDWARD MARTIN of Philadelphia read a paper with the following conclusions: (1) The conservative treatment of fracture of the patella is applicable to blow or tear fractures in which the separation of the fractures is not greater than one-half an inch when the knee is flexed to a right angle and in which there is no great joint tension. Conservative treatment consists in fixation for ten days, the application of adhesive strips to approximate the fragments, the use of elastic bandages to prevent inflammatory exudation, and the employment of massage and passive movements. (2) All fractures of the patella, independent of the amount of fragment separation, attended by marked immediate joint tension should be treated by the open method. (3) All fractures of the patella in which the fragments are separated more than one-half of an inch when the knee is bent to a right angle should be treated by the open method. The torn tendinous expansions of the quadriceps being closed by mattress sutures and the patellar fragments being united by silver wire, the insertion of the latter being facilitated by the use of a bone drill with an eye in its end.

**Retrodisplacements of the Uterus.**—Dr. J. MONTGOMERY BALDY of Philadelphia read a paper in which he said that retrodisplacements of the uterus were usually secondary to some other lesions, and in order to treat the condition successfully the primary cause must be removed. While there were cases that seemed to be without any primary cause, which were cured by the replacement of the uterus, he felt that the probabilities were that the real seat of the trouble was undiscovered, and that the case had been benefited without the remedying thereof, and would probably burst forth again upon any irritation, such as sexual relation incident to married life, puerperal sepsis or gonorrhœal infection. The most common associated condition is inflammation of the pelvis. In the way of treatment he believed the preferable operation was the intraabdominal on the round ligament, believing it was much more desirable than either Alexander's operation or hysterorrhaphy and that pregnancy could just as well occur thereafter as after either of the other operations.

**Some Observations on the Pathology and Treatment of Empyema.**—Dr. P. Y. EISENBERG of Norristown read a paper with this title. He remarked the fact that pleuritis was not only due to cold or injury, but might be developed by the extension of an inflammatory or other morbid process from some of the neighboring tissues to the pleural membrane, and that the suppurative form existed either as a primary or as a secondary infection. He outlined in detail the process by which the infection was communicated, and the pathological conditions present. This condition was usually preceded by three or four weeks of a pleuritis or pneumonia, its existence becoming manifest by a continued pain of an aching, throbbing character in the affected side—headache, thirst, anorexia, profuse perspiration, especially at nights, with a full bounding, but easily compressible, pulse, accelerated respiration, and a temperature of 102 to 103 or more, accompanied by rapid emaciation of the body and exhaustion; and in conjunction with this are the physical signs of effusion in the pleural cavity.

Dr. W. W. KEEN of Philadelphia said that the pyogenic infection was much less frequent than either the typhoid or the pneumococcus, and emphasized the need for especial care where there existed a mixed or pyogenic infection. He reported the case of a man who had pleurisy followed by rupture and discharge of a large quantity of very foul pus, the empyema being of about two and one-half years' duration at the time he came under the speaker's observation. At this time the cavity was very much contracted and very difficult to follow, resection of two ribs and removal of the parietal pleura being necessary. The flaps were inverted and united to the margin of the pleura, leaving a cavity 3 or 4 inches in diameter, which in eight weeks after the operation had entirely healed.

**Some of the More Infrequent Causes of Obstruction of the Common Bile-duct.**—Dr. LEVI J. HAMMOND of Philadelphia read this paper, in which he said that while the majority of cases of obstruction of the common duct resulted from infections through the gastrointestinal tract, there were many cases which so far as could be determined by exploration were in no way associated therewith, and he believed the lymphatics in other regions were a fertile source of infection. These cases were impossible of diagnosis before obstruction and very difficult even after. The anatomical construction of this region should be borne in mind, particularly the relation of the common bile-duct and the pancreatic duct, and the arrangement of the lymphatic glands. A case was reported of obstruction of the common duct following

pneumonia, which was believed to be due to lymphatic infection from the right pleura. Another case reported was caused by fibroid thickening with adhesions of the head of the pancreas to neighboring organs.

**The Results of the Surgical Treatment of Ascites Occurring in Cirrhosis of the Liver.**—Dr. HERMAN B. ALLYN of Philadelphia referred to the fact that Talma and Drummond were incited to the use of this operation by observing at autopsies that in the cases in which the anastomoses were most abundant the ascites was least, and they thought that if the adhesions could be increased and adequate collateral circulation secured, portal congestion would be relieved and the ascites cured. The usual operation consisted in opening the abdomen in its upper right quadrant, draining away the ascitic fluid and gently rubbing the parietal surfaces of the liver and spleen and abdominal wall with gauze sponges, and sewing the omentum to the margin of the abdominal incision. He believed the high mortality of the operation could be partly accounted for by the fact that many of the cases operated upon had been in a most desperate condition, and recommended that the case be carefully selected, as he did not feel, unless the patient seemed to be in a condition to survive the operation five or six months, the prognosis was favorable.

**Abdominal and Pelvic Surgery with Electrothermic Hæmostasis** was the title of a paper read by Dr. ANDREW J. DOWNES of Philadelphia, in which, he stated that the essential elements in his method were pressure and heat. He gave a full description of the instruments and the technique, and gave in detail the results of various operations—ovariotomy, salpingo-oophorectomy, hysterectomy, appendicectomy, and other operations on the stomach, intestines, and omentum in which he had used these instruments. He stated that he had not used a ligature within the last two years

(To be continued.)

**Contagious Diseases — Weekly Statement.** — Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 3, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 69 | 2 |
| Diphtheria and croup | 284 | 32 |
| Scarlet fever | 85 | 2 |
| Smallpox | ... | ... |
| Varicella | 15 | ... |
| Tuberculosis | 279 | 150 |
| Typhoid fever | 89 | 15 |
| Cerebrospinal meningitis | ... | 2 |

**Ovarian Tissue as a Hæmostatic in Hæmophylic Persons.**—S. Zavadier states that as in families of bleeders the females are usually spared from hæmophylia, they merely serving to transmit the tendency to their male descendants, it must be that one or other organ peculiar to the female exerts an important influence most probably on the coagulability of blood or less likely on blood vessels. The author inferred that the ovaries serve this function, from the fact that severe attacks of epistaxis are most common in females at the age of puberty and shortly after, when the functions of the ovaries are often getting deranged. He reports the case of a young woman who had a severe attack of epistaxis, to which she was subject. Styptics were of no use and plugging on the side of the throat was impossible because of the patient's sensitiveness. Two ovarian tabloids, five grains each, were prescribed every half hour in milk. The epistaxis stopped completely after four tabloids had been taken, and the patient was able to get up on the fourth day, whereas in previous attacks she had been laid up for a couple of weeks. A colleague successfully stopped a severe hemorrhage in a hæmophylic boy (whose bleeding from a small cut could not be stopped by a hypodermic injection of a ½ dram of defibrinated blood taken from the boy's grandmother. The author suggests treating cases of bleeding of hæmophylic persons with ovarian tissue internally, or with hypodermic injections of a healthy woman's blood.—*The Edinburgh Medical Journal.*

**Tonsillar Hemorrhage.**—Lawrence R. Ryan reports several cases of severe tonsillar hemorrhage, and from his experience he tabulates the plans of operation in the following order as productive of the most danger: (1) Removal by the bistoury, a plan which is almost obsolete. (2) Removal by the tonsillotome, which elevates the tonsil. (3) Removal by the flat tonsillotome. (4) Removal by the galvanocautery snare. (5) Removal by the cold snare. (6) Dissection, or tonsillectomy by the galvanocautery knife, requiring several sittings. He adds that he would hesitate now about removing by amputation the fibrous tonsils of people over twenty-five years of age, especially if they are densely fibrous.—*Illinois Medical Journal.*

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service during the week ended October 3, 1903:

### RADIUM: WITH A PRELIMINARY NOTE ON RADIUM RAYS IN THE TREATMENT OF CANCER.*

BY MARGARET A. CLEAVES, M.D.,
NEW YORK.

NOT only the scientific world, but the lay as well, listens with bated breath to the marvelous tales of radium; tales which, especially when accompanied by demonstrations of the apparently magical phenomena of this new element, seem more befitting fairy lore than abstruse scientific fact; and one can but wonder whether radium may not prove a veritable Aladdin's lamp to medical science as well as to physics.

"All nature is vibrating, from the lowest musical note to the highest pitch of the chemical rays," and in radium the highest form of etheric vibration is to be found.

The electrotherapeutist with his high-frequency discharges from vacuum tubes, his ultraviolet rays, his cathode and *x*-ray must, of necessity, have not only a scientific but a practical interest as well in radioactivity.

Radium, polonium, uranium, actinium, and thorium form a group of radioactive metals which have been extensively experimented with, and studied by Professors Becquerel, Thompson, Rutherford, Crookes, Lodge, Laborde, and Professor and Mme. Curie.

With radium, polonium, actinium, and thorium light is given off the moment they are created, without having to be stimulated by any form of heat, light, electricity, or any other form of energy so far as is at present known.

A vast amount of speculation and some interesting hypotheses have been evolved to exlain the phenomena observed in experimenting with these substances. "It is believed that from them much will be learned about the constitution of matter and the co-relation of the vital and physical forces, more, in all probability, than any substances which have been created since the world began."

Following upon the investigations into the phenomena produced on the interior and exterior of various kind of vacuum tubes to which great importance must be attached, came the discovery in 1896 of M. Henri Becquerel of the radiations emanating from uranium and which are known as Becquerel rays. A vast array of well-known names is associated with investigations into vacuum-tube phenomena, names which are veritable household words to the physicist, among whom may be mentioned, Varley, Hittorf, Crookes, Lenard, Röntgen, Hertz, J. J. Thomson, Goldstein, Schmidt, Ebert, Weichert, Geissler, Kauffman, Puluj, Perrin, Villard, Wien, Weidemann, Majorama, Birkland, Deslandres, Poincaré, Edison, Tesla, Rowland, Michelson, E. Thomson, Moore, Rollins, and Campbell-Swinton.

To Becquerel, however, the science of radioactivity owes its foundations.

*Read at the meeting of the American Electrotherapeutic Association, Atlantic City, September 22-24, 1903.

In 1898 Prof. Pierre Curie and Mme. Sklodowska Curie, when investigating the radiations from uranium discovered by Becquerel, found that some samples of pitchblende or uraninite, from which uranium is extracted, gave forth radiations much more powerful than any uranium they had found, having four times the activity of metallic uranium.

Painstaking research resulted in the discovery of a substance associated with bismuth and resembling it very much in its chemical characteristics. To this substance Mme. Curie gave the name of polonium, in honor of Poland, the land of her nativity.

Polonium is to be had in the form of a metal and in the form of a subnitrate. The metallic polonium resembles particles of nickel and the subnitrate is a white powder. The only specimen of metallic polonium in this country is in possession of Mr. W. J. Hammer, from whose exhaustive and interesting monograph[1] on radium many facts set forth herein have been gleaned. He also has the subnitrate, and both specimens possess an activity of 300. Just here it may be well to state that the radioactivity of uranium is taken as a standard of comparison, and polonium of 300 radioactivity, or radium of 7,000 radioactivity, means that the one is 300 and the other 7,000 times more powerful than the original radiations emanating from uranium or Bequerel's rays.

In the same year, 1898, Professor and Mme. Curie isolated a second substance from pitchblende, which was associated with barium and possessed many chemical and other characteristics of that substance. To this they gave the name of radium. In 1899 Debierne discovered actinium.

Radium, actinium, and polonium have a million times the activity of uranium, according to Professor Curie.

Gietel finds that polonium has both deviable and non-deviable rays, and Elster states that when it is placed in a vacuum it is found to be deviable by a magnet to a much greater extent than radium. The rays from actinium are also deviable, while the rays from radium are deflected from a straight line, differing in that respect from the Röntgen or *x*-ray.

Professor Curie regards radium as distinctly a new metal; it has never been found, however, in a metallic form, but it is to be had as a chloride or bromide.

Radium bromide is the strongest radium salt yet produced, and there is but little of it in existence, the amount having been estimated at as little as four grams. This statement probably refers to activities higher than 7,000. All radium of higher radioactivity than 7,000 has until recently been retained for the experiments of Professor and Mme. Curie and their associates, but recently information was received from Director Boulay of the Société Centrale that they expected shortly to put upon the market a preparation of radium, chemically pure, or nearly so, at a cost of $6,000 per gram. It is estimated by Professor Curie that the three years' work done in both Germany and France had, a few months ago, resulted in the production of but one pound of radium, including

all grades and qualities. There has been no radium on the market in this country, until very recently, save the German radium, which Professor Curie has never found to have more than 300 radioactivity. Recently, however, there has been imported, from the Société Centrale, the French radium prepared in the laboratories of Professor and Mme. Curie, of both 3,000 and 7,000 radioactivity, in sealed glass tubes containing a decigram each.

The radiations of radium have the power to penetrate opaque solids as does the *x*-ray. It has been demonstrated, however, by the work of Becquerel, the Curies, Rutherford, and others that there are three distinct types of rays emanating from radium, known as the "*A*," "*B*" and "*R*" rays. In the first instance it was pointed out by Rutherford that uranium possessed two distinct types of rays, "*A*" and "*B*," the former easily absorbed even by gases, whilst the latter are very penetrating but little absorbed by gas. In radium the "*A*" rays constitute the major proportion, are by far the most important class, and are the most active in the ionization of the gas which has been observed under experimental conditions. They are the rays which possess certain characteristics of the Röntgen or *x*-rays, and in a strong electrical field 45 per cent. of them have been deflected by Rutherford. They are readily absorbed and a thin screen of metal suffices to cut off the most of them. Hammer shows, among a considerable number of radiographs, one of a steel tool made by radium in twenty-four hours, acting through two thick *x*-ray plate envelopes, of a mouse made in twenty-four hours by laying it directly on the plate, and of a mouse in a trap, exposed for three days. In the latter the wooden part of the trap is transparent as with the *x*-ray. He also photographed a dead human hand, exposing it for eight days. A slight trace of the bones can be seen. It is supposed to be the first picture of the human hand made with radium. Through Mr. Hammer's courtesy I am enabled to show these radiographs to the association.

Rutherford estimates that the energy of the "*A*" rays is a thousand times greater than that of the "*B*" rays, and is also authority for the statement, that all radioactive substances, including polonium, as well as excitable bodies and their emanations, give out "*A*" rays.

The "*B*" rays are much longer, have greater penetrative power, are readily deflected by a magnet and correspond in every particular to the cathode rays.

With them electrified bodies are discharged by ionization of the air, photographic plates affected, etc. These rays are projected from the cathode at a speed approximating 70,000 miles per second. They were proven by Villard, in 1899, to be negatively electrified corpuscles or fragments of atomic hydrogen. These "corpuscles" so named by J. J. Thomson are shown by him to be the one-thousandth of the mass of a hydrogen atom. The "*R*" rays are the rays possessing the greatest penetrative effect, and they will excite or produce radioactivity at a distance of three feet or more. Rutherford's experiments show the relative penetration of the three classes of rays through aluminum sheets of varying thickness before there is a loss of half the intensity, which is formulated as follows:

"*A*" rays through a thickness of aluminum .0005 cm.

"*B*" rays through a thickness of aluminum .05 cm.

"*R*" rays through a thickness of aluminum .8 cm.

According to Professor and Mme. Curie, radium rays act in many ways like light.

They reduce silver salts, peroxide of iron, and bichromate of potash in presence of organic substances; while glass, porcelain, and white paper are colored by them, and yellow platino-cyanide of barium is transformed into the brown variety.

Becquerel, in referring to the chemical action of radium rays, states that white phosphorus is transformed into red in twenty-four hours, mercuric chloride, in the presence of oxalic acid, is reduced with the precipitation of calomel, and after long exposure the germinating power of seeds is destroyed. To the same chemical action the coloration of glass, porcelain, paper, and certain crystals, as well as the painful physiological effects, are due The coloring of glass by radium rays finds it counterpart in the coloring of *x*-ray tubes. Those who have tubes steadily in use, have noted that often they assume a violet tinge similar to the flask spoken of by Hammer, colored by radium rays. It is also found by Becquerel that radium rays have the same power as the electric spark, under exposure to heat, of restoring phosphorescent properties to a body deprived of them by overheating. The same is true of ultraviolet light.

Diamonds exposed in the dark to radium rays fluoresce and scintillate in the most brilliant fashion. False stones are therefore easily detected.

By its action gases are thrown into a state of vibration which causes the production of their characteristic spectrum. The phenomena of the emission of heat is unique and unprecedented, and a given specimen emits sufficient heat in an hour to melt its own weight in ice; while it maintains itself at a temperature of 1.5° C. above that of the sorrounding medium. Nor is it affected by a wide range of temperature, the emission of heat going on without perceptible variation, whether on a summer day or at the temperature of liquid air. A sample of bromide of radium, weighing 0.7 gram, tested by Dewar's method, was found to be capable of volatilizing an amount of liquid oxygen and hydrogen equivalent respectively to 6 c.c. and 73 c.c. of the gases measured at the ordinary temperature. In liquid hydrogen, however, radium shows that it is not always unaffected by external temperature, for, within a comparatively short distance of the absolute zero, the emission of heat, so far as present data can be relied upon, is augmented at the temperature of liquid hydrogen. This extraordinary phenomenon is increased in intensity at a point where all but the most powerful chemical affinities are in abeyance. This tremendous evolution of radiant energy goes on perpetually without combustion, without chemical change of any kind, without alteration of the molecular structure of the radium salt and without appreciable loss of weight. For one square inch of surface this loss of weight in ten million years is estimated at but one gram.

All of these facts are an apparent violation of the law of conservation of energy. From a close study of the phenomena exhibited by radium, Professors Crookes, Laborde, and Curie adduce an hypothesis that falls into harmony, not only with the law of conservation of energy but as well with the periodic law of atomic weights, or Mendeleeff's theory.

They discard the old atomic theory and tell us that each atom is composed of a definite number of infinitely smaller but absolutely identical units, "each in constant motion in its intraatomical orbit.

Thus the hydrogen atoms consist of 700 "ions," the oxygen atom contains 11,200 "ions" and gold 137,200 "ions" per atom. The 120,000 "ions" which compose a radium atom are in such a violent

ate of vibration or revolution in their orbits, that ey are constantly flying apart and escaping from e atom into the ether, similarly as meteors leave e solar system.[2] This active dissociation of intra-omical units is termed radioactivity.

Professor Lodge regards this atomical disintegra-n as the normal process of nature, but proceeding so slow a rate in the more stable atoms, that mil-ns of millions of centuries would be consumed in completion, while in radium the process is so pid it can be observed.

The Curies put forth two hypotheses as to the urce of the energy of radium. "One of these con-ts in supposing the atoms of radium evolving and ansforming into another simple body, and despite e extreme slowness of that transformation, which nnot be located in a year, the amount of energy olved in that transformation is tremendous. The cond hypotheses consists in the supposition that dium is capable of capturing and utilizing some diations of unknown nature which cross the space ithout our knowledge.[3]

The theory is advanced by Professors J. J. Thom-n and Rutherford that there is a succession of emical changes going on, causing the spontaneous rojection of larger masses of material at enormous elocities, and that while certain portions are con-antly dying out and becoming inert, other portions re constantly increasing in strength and power.

Substances which have been in contact with dium become radioactive and their radio-ctivity lasts for varying periods of time. Pro-essor Curie states that it is impossible for him o go near his instruments to make any measure-ents for hours, after being near radium, and those ho works with it, find it extremely difficult to eep their tools, instruments, and themselves free rom the radioactivity imparted by the radium. alling rain and snow are for a time quite powerfully adioactive, and lightning rods and even the leaves f trees also become radioactive. It was found by IcLennan that rain caught in a vessel and immedi-tely evaporated to dryness, imparted a radioactiv-ty to the vessel. Hammer found a piece of card-board, which had formed the box holding his radium, uminous in the dark after six days. This radioac-ivity was stimulated by burning magnesium wire before it.

Physiological effects: Becquerel, Gietel, the Curies, nd others have given important evidence as to the erious physiological effects of radium. Becquerel from carrying a specimen in his pocket for six hours received a serious burn on his abdomen. Hammer felt the effects for weeks from carrying a wooden box containing eight tiny tubes under his arm for several hours. He also experimented with an elec-tric torpedo in the Aquarium at Naples by placing six tubes of radium on the back of the fish, which is shaped like a flounder, leaving them there for twenty minutes.

Prior to doing this, both he and the members of his party had received powerful shocks from the tor-pedo's batteries. Upon removing the radium he tried for fifteen minutes to get a shock from the fish in the same manner as before but without success. He admits that the fish "might have been out of shocks," but the question which naturally arose was whether a partial paralysis had not been induced by the action of the radium rays. This seems more than plausible in view of the fact that Professor Curie found that a few milligrams of radium intro-duced beneath the skin of a mouse over the vertebral column produced death by paralysis in three hours; and tubes of radium placed in contact with the back of the neck of guinea-pigs have paralyzed these ani-mals in a few hours, according to the length of the exposure.

M. J. Danysz[4], in a report to the Academy of Sciences, states that the application of a tube containing a salt of radium to the skin produces an ulcer in from eight to twenty days. A few moments application is followed by a congestion of the human skin. When applied to the skin of a rabbit, destruction of the epidermis follows, but when applied under the skin there is only a feeble reaction on the epidermis. It seems to penetrate the muscles with difficulty. Danysz also found that the intestines and the serous surfaces, when the tubes containing the radium were introduced into the cavity of the guinea-pigs and allowed to remain for several hours, were but little affected, and no lesions produced comparable to those of the skin. Its action upon the nerve centers was noticed in all animals, subjected to experiment, but it was comparatively feeble in those whose osseous tissue protected the nerve centers. Application of the tubes containing the salt to the cranium caused paresis, ataxia, and convulsions, followed later by death. The same observer found that the salts of radium dissolved in distilled water, emits certain emanations which prevents the development of anthrax bacilli. E. Aschkinass and W. Caspari[5] found that the germs of the *micrococcus prodigiosus* when exposed to a radium preparation were effectively killed in about three hours by the action of the ray. The ocular phenomenon or sensation of light when a tube is held close to the eye or near the temple is one of the most familiar of the phenomena of this agent. This is attributed, by Hammer, to the phosphorescence of the pupil of the eye, and also to a possible effect on the nerve centers. Interesting in this connection are the observations of M. Javal[6] who suggests that blindness, with alteration of the retina, can be distinguished from that due to glaucoma or corneal opacity, because patients with the latter conditions see rays from radium as well as do those of sound vision. This would indicate, to the writer's mind, that the effect is upon the nerve center. Professor Curie is authority for the statement that he would not care to trust himself in a room with a kilo of pure radium, as it would burn all the skin from his body, destroy his eyesight, and probably kill him. From its physical properties and physiological effect, a therapeutic action is predicated. As yet there has been but little done.

M. Danlos[7] reports a case of lupus of the face exposed at two points to the action of a salt of radium which had a radioactivity of 19,000 for from twenty-four to thirty-six hours. The result was disappearance of the disease with the formation of a smooth, white cicatrix, blending into the surrounding normal tissue.

M. M. Hallopeau and Gadaud[7] report that too prolonged exposure to the emanations from radium led to atonic ulcerations which lasted from five to six months. Dr. Blandamour has also used radium in lupus. His best results followed the use of salts with a radioactivity of 5,200 and 19,000 respectively.

The exposures were made from twenty-four to forty hours, and were followed by profound erythema with maceration of the tissues exposed and even ulceration. The recovery was perfect and the cosmetic effect good, the resulting scar being white, smooth, and soft. By modifying the power of the radium and shortening the exposure, he expressed the hope that the desired effect might be obtained without ulceration. Recently there were two cases reported to the Viennese Society of the Imperial Academy of Science,[8] which had been submitted to

the action of radium. One, a man, aged sixty-two years, had been repeatedly operated upon for cancer of the palate and lip, but with no benefit. Further operative measures had been declared useless. In the published report falling under the writer's notice, the radioactivity and technique were not given, but a bromide of radium was used. The tumors gradually and completely disappeared. The patient was treated in the clinic of the late Professor Gusenbatter. The second case was one of melanosarcoma, which was also reported cured.

Equally interesting is the case of Mr. Mackenzie Davidson at the Charing Cross Hospital, London. A recurrent epithelioma of the nose, rodent ulcer type, unsuccessfully treated by the *x*-ray, was exposed for a short time to the action of radium. Four exposures, aggregating an hour, were given at intervals of a few days. In three weeks time healing was established, and in six weeks, after two other applications, the cure was complete.

For two years the writer has entertained the thought of trying the radium emanations in the treatment of malignant diseases, but owing to the limited supply, as well as the great expense, it was only recently made possible.

On September 15, through the courtesy both of Prof. Charles Baskerville, Director of the Laboratory, Department of Chemistry, University of North Carolina, and Eimer & Amend of New York, the writer was enabled to use one gram of bromide of radium contained in a sealed glass tube, and having a radioactivity of 7,000 in the treatment of two cases.* One, a case of sarcoma involving the left cheek, entire buccinator region, and the mucous membrane of the lower left maxillary region, from the extreme angle of the jaw, extending upward and along the ramus of the jaw; the other, an inoperable primary pelvic case of epithelioma, involving the cervix, anterior and posterior vaginal walls, almost to the introitus; rectum, bladder, and both broad ligaments. Both cases have been under treatment, the first for five weeks, the second for three months, by means of the *x*-ray and ultraviolet light, and both had been declared inoperable by the best surgical talent.

The case of sarcoma had been treated by external applications of the *x*-ray, twelve exposures for one month prior to coming under the writer's care, and not only without improvement, but with a steady loss. Since under care, now five weeks, the *x*-ray has been applied to the interior of the mouth as well as externally and applications of ultraviolet light, through focusing quartz lenses from a 25 ampere arc, made as well. By this treatment the patient had been relieved of the intense pain for varying periods of time, but the relief did not persist. When first under treatment he gained three pounds. This he had lost, pain and distress were constant, facies, anxious and worn, sleep very much impaired, appetite poor, progressive loss in weight, intense headaches. The ulcerated area was larger, and on September 11 was covered with a dirty grayish exudate, foul to a degree, with ragged and necrotic edges.

The growth involving the region of the buccinator muscle was tense, hard, and extremely painful. Just inside the mouth under the upper lip, left angle of the mouth, there were two prominent tubercles; unable to open his mouth, save for a scant half an inch, and impossible to take anything but liquid food. On the night of the 13th and the morning of the 14th of September he had a severe hemorrhage. Duration of the disease is placed at one year. Active evidences followed removal of an upper tooth one year ago. Tooth removed because of pain. Disease has steadily progressed since that time. September 15, 1903, the growth involving the left buccinator region was exposed to the radiating surface of one gram of radium bromide, of 7,000 radioactivity and contained in a sealed glass tube. The tube was held by means of a pair of long dressing forceps at three-quarters of an inch from the skin for ten minutes, followed by a five-minute exposure made in the same manner to the skin over the ulcerated area. Upon the suspension of treatment the patient said he was relieved, and that he could open his mouth with greater ease and comfort, and that he felt better than any time since coming under care. He reported, on the morning of the 16th, that he had slept better the preceding night than for three months, that he suffered no pain and was only wakened by the dribbling of the discharge from his mouth. On the way to the writer's office he had a feeling of faintness which was ascribed to his weakness and the intense heat and humidity. Appetite better, the 15th after treatment and also the morning of the 16th. Opened his mouth the merest trifle wider and without pain. Practically no odor and but little discharge, no pain save a little upon deglutition, feels well.

Physical Examination: Facial expression bright and pain free, looks rested; indurated tissues softer and more yielding to touch, softness characterizing the more superficial part of the induration; mucous membranes pale (pallor since use of radium), ulcer not so dirty looking but still gray in appearance. September 16, radium rays used as before, the surface exposure lasting but ten minutes; then the tube of radium salts was placed in a small test tube, the upper lip raised and an application of two minutes made at the upper left angle of the mouth, directly to the tubercles.

September 18, 1903. In response to the morning salutation, instead of the former "not any different" or "I am in great pain" the response was prompt and cheery "I am very well." Restless in the night, but no pain, discharge thinner, diminished in quantity and of different odor, *i. e.* not characteristic. Present condition, no pain save a slight sticking pain to left of left alæ nasi, indurated tissues much softer, softness extending deeper than on the 16th. Ulcer clean and bright, red at its base, edges still somewhat ragged, entire surface of ulcerated area bathed in an exudate serous rather than characteristic gray. The upper lip at the left angle before immobile with prominent tubercles is now readily handled, the tubercles are much smaller and the mucous membrane is smoother and of a more healthy color.

Five days subsequently the patient was still almost entirely free from pain and was conscious of the cavity inside the mouth. This he had not spoken of at any time before. As there has been a good deal of numbness in all the affected tissues, it is thought that this simply indicated a return to normal sensibility, as the anæsthesia was better elsewhere. Discharge still about the same in quantity, thin and of a serous nature; no characteristic odor, sleep improved; appetite fair; induration softer than at previous visit; mucous membrane has lost the profoundly anæmic appearance which followed upon first treatment. The reaction established in the ulcerated area has passed, the circulatory conditions are less good and there is more gray exudate with ragged edges.† The usual *x*-ray treatment was

*Since reading this paper a third has been added to the list, a recurrent epithelioma, rodent ulcer type, involving loss of scalp and skull plates (the latter from arsenical paste) of from four to five inches in lateral and antero-posterior diameter. This case was treated September 25 for ten minutes.

†September 25, 1903 Better, has gained one pound; no pain until September 24; no odor; discharge as before; ulcer cleaner; edges smooth; normal color, induration less.

given at this time, as the writer had been obliged to return the tube of radium to Professor Baskerville.

The pelvic case had been under care for three months and has improved to date under the combined influence of the *x*-ray (internal applications entirely) and ultraviolet light. Infiltration of vaginal walls is largely absorbed, hemorrhage under control, discharge also and the foul odor has entirely disappeared. Healing has taken place in the ulcerated area involving the cervix and the right posterior fornix. The patient's general condition is much improved, there is no characteristic pain, no cachexia, no loss of weight, her functions are well performed and she eats and sleeps well. There is, however, a discharge of blood from the rectum upon defecation and now and then at other times. Because of this, and believing that the radium rays would penetrate more deeply than the *x*-ray, the radium was used.

Prior to its use a physical examination was made showing elastic vaginal and rectal walls, no bleeding from the manipulation, no discharge, no odor, no ulcerated tissue, no pain, but the cervix uteri and adjacent vagina through the glass water-jacket of a vaginal *x*-ray tube, inserted to contain the tube of radium, were seen to be intensely congested, just ready to bleed, and streaks of blood were numerous, especially from the right fornix and posteriorly. In this water-jacket, closed at its distal end, the tube containing the radium bromide was placed and allowed to lie on the posterior surface of the water-jacket for five minutes. It was then held five minutes more near the anterior surface of the tube, because of the vesical involvement.

September 16, 1903, the cervix uteri was found to be completely blanched and also the vaginal walls, with here and there tiny little punctate spots of bright red, not larger than the smallest pin head. There was no discharge, no odor, and no pain. The writer questioned the advisability of making another exposure at this time, but as it was the only opportunity of doing so before returning the radium to Professor Baskerville, a five-minute application was made as before.

September 18, 1903. Speculum examination showed the cervix uteri and vagina intensely congested and bleeding; no treatment given. It is evident from the reaction that a mistake was made in reapplying the radium in this case on the second day.

September 21, 1903. Five days subsequent to the use of radium, no bleeding, no odor, no discharge, no ulceration, and vaginal and cervical mucous membrane normal in appearance. General condition good, but complaining of some vague discomfort, which may be attributed to the fact that her occupation necessitates much standing and walking. There has been no bleeding from the rectum since the radium was used.*

This report is made because, taken in connection with the experience of others, it seems to foreshadow an important place in medicine for radium. The writer offers no opinion as to the outcome of these two cases. They will be carefully watched and ultimately reported. The technique evolved is given, in the absence of any knowledge on the subject. It may not stand the test of time. Further experience can only prove this. There is absolutely no guide for the therapeutic applications of radium, and the writer preferred to err on the side of least danger to the patient. The profound physiologic action obtained would seem to indicate that the more powerful activities and long exposures are not necessary.

*September 28. Is looking and feeling well. No symptoms; still no bleeding from rectum since radium first used, two weeks since.

Of the three sets of rays in radium "*A*," "*B*," and "*R*" evidence points to the identity of the "*A*" ray with the Röntgen or *x*-ray, in the matter of penetrating opaque bodies. This and subsequent facts suggest to the writer's mind, a corroboration of the position taken by the Drs. Shields,* that it is not the *x*-ray, but the cathode ray which establishes physiological action and secures a therapeutic effect. To *x*-rays however produced, whether from an excited *x*-ray tube or a radium salt, the power of penetration of opaque bodies is then due. In the "*B*" rays a higher vibration is reached analogous to the cathode rays, while in the "*R*" rays a still higher degree of vibration is attained, capable of a more powerful chemical action and profounder physiological effect. This is what we seek in combating diseases of the nature of cancer. In a daily experience with these cases the writer has come to feel that if a higher, more penetrative and a more active chemically disorganizing vibration than is obtained from an *x*-ray tube could be applied, in a *lethal dose*, to the cancer cells, better results would necessarily accrue. So much is accomplished with the *x*-ray that one can but feel that an energy of the same kind, but of greater intensity, would do more. In establishing the treatment by means of radium rays the purpose would be best met by a full dose, whatever that proves to be, in order to act destructively upon the foci of disease.

The fact that radium emits rays of a greater penetrating power and of a higher vibration than the cathode rays, *i.e.* the "*R*" rays taken in connection with the change in appearance and relief obtained in the writer's case of sarcoma and the cure of the cases reported, stimulates the hope that in radium a therapeutic measure of value over and above the *x*-rays is at command. In the case of sarcoma the best resources of excited *x*-ray tubes has been faithfully tried, even to the production of an *x*-ray dermatitis, but up to the time of the use of the radium he was rapidly losing ground. Unless radium should prove for him an Aladdin's Lamp of more than fabled power, he is doomed.

There are submitted herewith two tubes of radium bromide, one containing a decigram of 3,000 and the other a gram of 7,000 radioactivity. At night, in the dark, they look like glow-worms as they lie on my study table. They can be placed within the accessible mucous cavities, according to the location of the disease, within the nose, uterus, or urethra, and a device could unquestionably be constructed permitting the placing of one in the œsophagus or stomach even, if it is found that a mucous membrane contact is the better one. In breast cancer a puncture could be made with the electrocautery, in order to secure a bloodless opening, and the tube could be carried directly within the malignant mass.

To the over-tired *x*-ray machine and tube worker, the thought of securing the same, and perhaps better, results with one of these quiet, inoffensive, and unaggressive tubes of radium salt is entrancing. The use of radium can never be common, not alone on account of the initial expense, but because of its scarcity. The tube with which the writer's work has been done is valued at $200. Future work will be done with the same radioactivity.

Just here, as showing not only the unity of scientific interest but the universality of humanitarianism, is appended a letter received from Professor Baskerville on the 21st.

My Dear Doctor: . . . I am very glad you kept the radium long enough to make some use of it, and I wish to say right now that while I wanted it here and shall need

it off and on, if you can save the patient about whom you write so interestingly, by its use, wire me and I will send it back to you.

Yours very truly,

CHARLES BASKERVILLE.

# STRICTURE OF THE MALE URETHRA.

### DEFINITION, ETIOLOGY, PATHOLOGICAL ANATOMY, SYMPTOMS, AND CLINICAL COURSE.

BY HENRY G. SPOONER, M.D.,

NEW YORK.

A STRICTURE is a narrowing of the normal dilatable diameter of the urethra, caused by organic alterations in its wall. This lessening of the normal dilatability advances slowly and progressively, causing secondary affections of the entire urinary tract.

In this definition we do not include transitory conditions, such as the so-called inflammatory strictures, which are caused by swelling and œdema of the mucous membrane. In the acute stage of gonorrhœa we have such an intense swelling of the mucous membrane of the urethra that the patient can pass his urine only with difficulty. In this case we have a narrowing of the normal dilatability of the urethra, but the hindrance to micturition gradually disappears without leaving any permanent narrowing of dilatability.

When the folds of the urethra, are encroached upon from without by abscesses, hemorrhages, or by an enlarged prostate, we speak of such conditions as compression strictures.

Under all circumstances urethrospasmus is a transitory phenomenon. This spasm of the urethra is a reflex action, caused by strong irritation in the urethra or its vicinity. There is no more reason for speaking of this condition as a stricture than there is in the case of spasmus glotticlis, or spasm of the rectum. The spasm always occurs in a reflex manner, in contradistinction to the sympathetic purely nervous urethral spasm, which comes on under psychical influences, such as anger, shame, or fright.

The spasm renders a certain hindrance to the passage of a sound that is just as apparent as if there were a true organic stricture.

Thus it can be seen we reserve the term of "stricture" for an organic and permanent narrowing of the normal dilatability of the urethra.

From an etiological standpoint strictures are divided into two groups: (1) Inflammatory strictures, and (2) traumatic strictures.

As chronic gonorrhœa is the most evident cause of the first group, these strictures are commonly called gonorrhœal strictures.

Since Sir Henry Thompson proved statistically the number of strictures that were caused by a chronic gonorrhœa, all the later authors have taken this view. Thompson gathered 220 cases of stricture of the urethra. In 164 cases gonorrhœa was the only cause.

As not every clap leads to a stricture, we are compelled to assume that harsh medical treatment causes one patient to get a stricture, while his more fortunate contemporary who is more scientifically treated, escapes.

The early use of strong solutions of corrosive sublimate, silver nitrate and chloride of zinc used to abort the disease have been found to be particularly responsible for the development of strictures.

The injections now used, such as the newer silver compounds, by preventing the chronicity of gonorrhœa, prevent the formation of strictures.

Tertiary syphilis, in the form of a gumma, leads to the formation of a stricture. Sometimes the healing of a tuberculous ulcer of the urethra causes the same result, but these conditions are rare.

We next come to traumatic strictures. Blows or falls on the perineum arising in all possible ways may lead to the formation of strictures. A tear in the urethra may occur with or without outer wound. A callous forms and leads through the contraction of scar tissue to the narrowing of the normal dilatability of the urethra at the location of the injury.

Fractures of the pelvic bones are very often complicated with a torn urethra. Nearly all these injuries pass through the pars-fixa urethræ, while the pars pendula is hardly ever involved—the pars pendula may be ruptured in cases of chordee, owing to an attempt of the patient in his anguish to straighten the curved penis.

Bullet wounds of the urethra are very rare—there were only 105 cases in our civil war. In the Franco-Prussian war there were only eight cases. In these cases the prognosis is very unfavorable, as grave complications nearly always set in.

Any foreign body that passes through the urethra, such as a stone from the bladder, or any instrument or article that is introduced into the urethra, may cause a tear which, when cicatrization sets in leads to the formation of a traumatic stricture.

*The Pathological Anatomy.*—Strictures of the urethra were known to classical antiquity, but the most peculiar theories were advanced concerning their origin and pathological anatomy. The formation of what was called "proud flesh" and "wild flesh" were regarded as the pathological changes.

John Hunter was the first man to hold more correct views. He differentiated the permanent urethral strictures caused by structural changes in the urethra from the purely spasmodic and from those caused by compression of the urethra by outside growths.

With the histological work that has been done during the past twenty years concerning chronic gonorrhœal urethritis and strictures of the urethra, our knowledge of the pathology of strictures has advanced. The works deserving particular attention are those of Dittel, Wossidlo, Oberländer, Finger, Wasserman, and Halle.

To-day we know that the gonorrhœal stricture rests on the same pathological process as chronic gonorrhœal urethritis, and that both diseases can only be gradually differentiated. In other words, the gonorrhœal urethritis is the first stage of a pathological process whose end is that of the formation of cicatricial tissue.

The gonorrhœal inflammation attacks (1) the mucosa urethræ. From this initial source of infection the chronic inflammation stretches out to (2)

the submucous connective tissue, and then to (3) the corpus cavernosum urethræ.

The final result of this process is the formation of a tough fibrous connective tissue, detracting from the normal dilatability of the urethra.

Macroscopically, the thickening of the urethral wall may be seen. Its lessened dilatability can be seen by the endoscope. The form and normal

Fig. 1.

properties of the urethra are altered, and, indeed, not only at the narrowest diameter of dilatability, but also on the folds of mucous membrane of the urethra that have only been attacked by a very mild grade of the chronic inflammation.

In conditions of rest the mucous membrane of the normal urethra lie in narrow folds one upon the other. The normal urethra has a caliber only when urine or seminal fluid passes through its canal,

Fig. 2.

thus stretching out the folds of the urethra according (1) to the pressure exerted; (2) the elasticity of the urethral walls, and (3) the resistance caused by the orificium externum.

On looking at the folds of mucous membrane through the endoscope, we can learn how these folds are normally arranged in the different parts of the urethra.

The meatus externus through which we can see

Fig. 3.

the urine come, is placed horizontally. The endoscope when inserted inside the meatus and anterior to the pars navicularis, is composed of three folds forming a triangle, the two longer folds making the apex of the triangle above, the under fold has begun to form in order to make the transition from the longitudinal opening at the meatus to the transverse position of the folds found in the pars navicularis of the urethra, as shown in Figure 1.

When the endoscope is in the middle of the pars navicularis, the upper two folds shown on last figure will be found to have come together, and the transverse fold has lengthened, giving the transverse folds found in the cavernous portion of the urethra, as shown in Figure 2.

Fig. 4.

In the middle of the penile portion of the urethra, on the upper wall, can be found the openings of the glands of Littré, as can be seen in Figure 3.

When we come to the pars membranacea we find the folds placed in a horizontal position, as we found them placed at the meatus externus. This is a very important fact to bear in mind in any endoscopic study of the urethra, as by bearing this fact in mind

Fig. 5.

we can tell when we are entering the posterior urethra, Figure 4.

In the middle of the prostatic urethra the folds round over the verumontanum, as seen in Figure 5.

Just before we enter the neck of the bladder, the folds can be seen going out from the middle of the picture, as seen in Figure 6.

Thus it can be seen that in a state of rest there is no opening in the urethral canal, therefore we cannot

Fig. 6.

correctly speak of the caliber of the normal urethra, as the folds of the urethra rest one upon the other; second, that the folds of the urethra, although differing in size and color in different urethras, present definite formations in the different anatomical divisions of the urethra.

In the chronic inflamed urethra the elasticity

and the picture of the folds of the mucous membrane are altered so that a more or less swollen lumen of the urethral canal can be noted. If the chronic gonorrhœal inflammation has developed a stricture then the urethra assumes the form of a canal, and its form will vary according to the contraction of the various structural changes. On endoscopic examination a stricture has the form of a small hole or gaping cleft with non-elastic walls of variable forms, as shown in Figure 7.

FIG. 7.

It is possible to classify a number of certain anatomical types of stricture: (1) Often the stricture is cylindrical; (2) More often still it is funnel-shaped; (3) In many cases it is in the form of a ring embracing the whole circumference of the urethra; (4) The half-ring formation is more common. Aside from the forms mentioned there are a great many irregular forms that cannot be grouped in any of the above divisions.

When, as is often, the case multiple strictures are formed, they generally belong at first to the same variety, but they soon become differentiated in form.

By small cicatricial alterations the urethra loses its elasticity, and in extreme cases it is scarcely possible to see the opening with the naked eye.

The axis of the stricture is not always in the same plane as the axis of the urethra. A stricture can follow a winding course and then have various axes. The opening of the strictured canal is not always in the middle of field of vision; it lies very often excentrically. The length of the stricture is generally not marked; it depends upon the amount of tissue involved in the pathological process that caused it. However, the length of gonorrhœal strictures is seldom greater than one centimeter.

The number of strictures in the urethra are dependent on their etiological cause. While traumatic strictures are single, gonorrhœal strictures on the contrary are often multiple. However, it is rare that more than three strictures can be found in the urethra.

The position of the stricture is dependent upon the situation of the pathological process that caused it. The traumatic stricture develops where the urethra was torn. As wounds which lead to tears of the urethra occur mostly in the region of the perineum, traumatic strictures occur most often in this location.

The gonorrhœal strictures develop in the place or places where the chronic inflammatory process has reached its greatest intensity.

Sir Henry Thompson investigated 320 anatomical preparations in order to find out the most frequent position of gonorrhœal strictures. For the purpose of classification he divided the urethra into three divisions.

1. Embraces the region of transition between the bulbous and membranous parts, embracing 2.5 centimeters in front, 1.8 centimeters behind this line of division.

2. From the forward boundary of the first division to 6.3 centimeters from the meatus.

3. From the meatus externus to 6.3 centimeters or to the forward boundary of division 2.

The strictures are divided into these arbitrary divisions, according to Thompson, as follows: Total number of strictures, 320. In region 1, 215, or 67 per cent; in region 2, 51, or 16 per cent; in region 3, 54, or 17 per cent. Of these, 185 had only one stricture in region 1; 17 had only one stricture in region 2; 34 had only one stricture in region 3. It was found that there were 8 cases in which all three regions were strictured, 10 cases in which strictures were found in regions 1 and 2, 10 cases in which strictures were found in regions 1 and 3, 10 cases in which strictures were found in regions 2 and 3.

Thompson ascertained that in the museums of London, Edinburgh, and Paris there were only two specimens of stricture of the prostatic urethra.

Rollet gives the following measurements of the dilatability for the different parts of the male urethra. Orifice, 7–8 mm., 21–24 Charrière; fossa navicularis, 10–11 mm., 30–33; behind the latter, 9 mm., 27; middle of pars cavernosa, 10 mm., 30; bulb, 12 mm., 36; pars membranacea (middle), 10 mm., 27; pars prostatica (beginning), 10 mm., 30; middle of same, 15 mm., 45; posterior part of same, 11 mm., 33.

Thus it can be seen that next to the orifice the bulbo-membranous junction is one of the least dilatable parts of the urethra.

Endoscopy has, however, taught us that there are a much greater number of intensely chronic inflammatory changes of hard infiltrated formation in the pars anterior than were formerly recognized.

From the above-mentioned figures of the dilatability of the urethra it can be seen that we cannot rule out the presence of a stricture in cases in which a sound 16–20 Charrière has been passed easily through the urethra.

In the anterior portion of the urethra we find a great many strictures of wide caliber as shown by Otis. Finger in his monograph on this subject has pointed out the importance of recognizing these strictures of large caliber at an early date in their formation, as an important aid to preventive treatment.

Passing now to the macroscopical examination of the changes caused by cicatricial tissue, we find important periurethral changes. The section of mucous membrane is much thicker in the location of the stricture, whiter and harder than in the other parts of the urethra. There no longer exists any sharply marked boundary between the mucous membrane and the corpus cavernosum. In severe cases the mucosa and the corpus cavernosum are changed into a hard callus. The cavernous connective tissue has lost its normal appearance. It appears homogeneously hard, of an equally pale color, atrophied and sclerosed. The normal vascularization has disappeared to a greater or less extent on the surface. Microscopically we find a change in the strictured urethra in the form of an alteration of its epithelium.

In the first grade of inflammation we find epithelial alterations, consisting of a thickening, swelling, and partial desquamation. The epithelium has a tendency to change from the normal cylinder epithelium into pavement epithelium.

Finger has differentiated three types of pavement epithelium. (*a*) It resembles that of mucous membranes with pavement epithelium, *i.e.* it consists of an undermost layer of cubical cells, several layers of polygonal and an upper layer of pavement epithelium. (*b*) The epithelium is epidermoidal; consists of a lower layer of cuboidal cells, followed

by several layers of polygonal or spindle-shaped cells analogous to the reti malpighii. These cells constantly grow larger and flatter toward the surface. (*c*) The epithelium is like that over cicatrices, and consists of several layers of very flat pavement epithelium.

This conversion of cylinder into pavement epithelium, which causes a xerosis of the mucous membrane, is connected with the changes in the subepithelial connective tissue.

The first type we find in fresh cases, the second in cases in which old round-celled infiltration has taken place, the third in cases in which thick, hard connective tissue has been formed.

The changes of the subepithelial connective tissue in the early cases of chronic urethritis consist in an infiltration of mononuclear and epithelial cells.

"The older this infiltration becomes, the more spindle cells can be seen. The connective tissue substance becomes thicker and harder, and a connective tissue mass is formed that resembles anatomically the callus, but caused not by ulceration, but by a connective tissue hyperplasia"—Finger.

The chronic infiltration of urethritis can remain on the surface or it can press in as a periglandular infiltration into the deep parts of the corpus cavernosum the length of the glands of Littré. There develops in the cavernous connective tissue through the process of small cell infiltration a fibrous connective tissue that changes the mucosa and corpus cavernosum into a thick, broad, contracting callus.

Where the process existed in the first stage the trabecular of the corpus cavernosum appears thickened and infiltrated, with round and spindle cells. The more the fibrous degeneration advances, the more the infiltrated tissue shrinks, and the more the cavernous tissue is obliterated. The compact, newly built tissue which has taken the place of the cavernous tissue shows here and there the altered tissue elements (the elastic fibers, muscles, and blood vessels embedded in the fibrous mass).

The blood vessels of the corpus cavernosum are attacked by an endoperiarteritis. This process advances until the vessels are obliterated.

The glands of the urethra are often no longer to be recognized in the lumen of the stricture. They have played an important part by their production of deeply seated tissue changes. By conveying the inflammatory process to these deeper regions, the glands themselves become atrophied, destroyed, embedded in the fibrous tissue, the production of which they have caused.

These deeply seated calluses, the result of the chronic urethritis, are the foundation of the stricture. We can therefore see that the stricture has been caused by the chronic cirrhosis caused by the chronic urethritis, complicated with periurethritis and cavernitis.

In the case of traumatic stricture an unyielding connective tissue develops in the walls of the urethra and surrounding tissue, and follows the same course that scars do in other parts of the body.

*Symptoms and Clinical Course.* — While the traumatic stricture develops in a seemingly short period after the urethra has been torn, a long period of time separates gonorrhœa and the first symptoms of the stricture.

Generally four to eight years after the clap the patient gradually appreciates that there is a narrowing of the urethra. This narrowing slowly and insidiously develops, causing a painful and slow urination. A mucopurulent discharge may begin, notwithstanding the fact that many years have passed since the cessation of the acute gonorrhœa.

A small amount of secretion may be unobserved. Generally the attention of the patient will be called to this chronic secretion through the onset of other symptoms, such as a narrowing of the urinary stream.

Patients have mostly regarded the little morning drops of pus as a matter of no importance, and this is perhaps the reason that this symptom is paid so little attention to.

This little morning drop is the sign of the long existence of the chronic gonorrhœal inflammation. This symptom can disappear for a long time, but it may start up again after excesses in baccho or venere. The former clear, watery secretion again becomes cloudy, yellow, and more purulent.

In spite of the constancy of this secretion in the morning, the patient does not begin to realize that he has a stricture until his stream has become somewhat diminished in volume. Very often the patient does not consult the doctor until it becomes necessary to strain very greatly to empty the bladder.

The symptoms come on slowly, and therefore gradually increase in severity.

The patient first notices an alteration in his stream of urine. In the case of young people, in whom the expulsive strength of the bladder is good, the stream will be regular in caliber for a longer time, as the regularity and strength of volume are dependent just as much on the powers of the bladder as on the resistance caused by the relative narrowness of the meatus externus urethræ.

When the quantity of urine contained in his bladder diminishes, as at the end of the act of micturition, the form and projection of the stream are altered. The same condition may arise when we have a full bladder with diminished expulsive force.

Therefore, while observing the stream of urine, we must consider: (1) The strength of the bladder, particularly toward the close of urination; (2) the dilatability of the urethra, and particularly the amount of resistance caused by the orificium externum; (3) the other pathological changes of the urethra that cause an increased resistance to the flow of the stream, such as hypertrophy of the prostate.

In proportion as the expulsive force of the bladder is lessened and the resistance of the urethra is increased, so will the bow that the urine normally makes when expelled be foreshortened and the stream narrowed.

In the case in which a stricture of wide caliber is situated in the anterior part of the urethra, there will scarcely be any change. If the opening through tight strictures is more on the upper wall, the stream divides, while a part of the urine drops down in drops on to the floor. This bifurcation of the stream has been noticed in strictures of the bulbomembranous junction, and particularly when a mucous plug has blocked the meatus. In this case the divided stream appears at the beginning of micturition, but as soon as the plug is eliminated it assumes again its undivided form.

If the urine at the beginning comes only a drop at a time and then into a thin stream with a short bow, there is a long and narrow stricture in the forward part of the urethra.

The further back the stricture is located, the thicker is the stream and the more foreshortened is the bow. When the stricture is located at the orificium externum we have a splashing urethral stream. As a stricture contracts the stream of urine becomes thinner, then only a drop of urine comes at a time, and finally we have a total suppression.

As the stricture narrows, the patient must take more time to empty his bladder. He seeks, first by assuming different positions, secondly by straining, he endeavors to pass his water more easily. He brings the accessory muscles of the abdominal wall and thorax into a state of rigidity in order to increase the pressure on the contents of the bladder.

As the stricture becomes narrower, the efforts the patient must make become increased. As a result of this great pressure brought to bear on the bladder, gas and fæces are expelled.

As this great straining is increased, the face becomes plethoric, and even a hemorrhage of the brain may be caused. An inflammation develops in the neighboring parts of the urethra and bladder, causing secondary complications. The urine is now passed with great difficulty, owing to the painful tenesmus. The pain persists not only during micturition, but persists afterward, shooting into the pelvic regions and testicles. The agony of the patient caused by this painful strangury gives him no rest. Yet in spite of this straining and agony the patient cannot entirely empty his bladder. An increasing amount of residual urine is left in the bladder, and entire strangury results. As the bladder tries to meet these extra demands always in an increasing ratio, it loses its power of contraction, causing the amount of residual urine to increase. Through a constant dribbling of the urine an eczema results to add to the suffering of the patient.

As regards the general constitutional symptoms, the patient gradually loses in weight and strength, as his appetite diminishes owing to his continuous suffering and sleepless nights.

25 West Forty-fourth Street.

## THE NEED OF ORGANIZED EFFORT IN THE PREVENTION OF THE SPREAD OF TUBERCULOSIS.*

By F. M. POTTENGER, Ph.M., M.D.,
LOS ANGELES, CAL.

PRESIDENT OF THE SOUTHERN CALIFORNIA ANTITUBERCULOSIS LEAGUE, CORRESPONDING MEMBER OF THE CENTRAL INTERNATIONAL BUREAU FOR THE PREVENTION OF CONSUMPTION, ETC.

In this age of multiplicity of organizations, it is well for us to inquire whether there is need for an organization such as the Southern California Antituberculosis League, and I have chosen to make the answer to this question the burden of my remarks at this the first public meeting of our society.

Tuberculosis is not a newly discovered disease. Even before the Christian Era it was credited with being man's greatest enemy. Down through the ages it has strewn its path with suffering and death. The discovery if its cause and nature, however, brings the subject before us in a new light, and gives us our first hope of staying its progress. As long as the old crude notions of its heredity were held, it was not thought possible to prevent it; but when Robert Koch in the year 1882 showed that the disease was caused by a specific germ, he paved the way for its eradication. If the measures which are now known to science were enforced, it would be possible to free the world of tuberculosis. Professor Nocard said: "With suitable assistance I will rid France of bovine tuberculosis in eight years." What can be done in cattle, can be done in man; but to accomplish the eradication of human tuberculosis is more difficult. Diseased cattle we can kill, but diseased men we must educate to a realization of the responsibility which rests upon them.

It has been estimated that tuberculosis causes 2,000,000 deaths annually, that is nearly four per minute. In the United States, where the mortality is among the lowest of civilized nations, it kills nearly 150,000 people a year, or one every three and one-half minutes. According to the Public Health Reports for the year ending December 31, 1900, there were in eight cities and towns in the southern part of California, having an estimated population of 147,449, five hundred and twenty-one deaths from tuberculosis, or a death rate of ten per week. This means that since Koch's discovery of the cause of tuberculosis, which showed the disease to be communicable, and likewise preventable, it has been allowed to produce death in a number of individuals which is far greater than the entire population of these United States. In the United States, in that time, there have died nearly 3,000,000 people from tuberculosis, or twice the present population of California. Let us compare this loss of life with that caused by the Civil War. It is estimated that that sad conflict caused the death of about 300,000 men; tuberculosis, on the other hand, causes the death of 600,000 individuals every four years. Think of it! An army of 150,000 of our fellow-countrymen destroyed annually by tuberculosis, a preventable disease. Is this not enough to warrant the formation of our society?

Appalling as these figures are, they might fail to secure your interest were it not for the fact that this disease is so widespread. What one of us can say that we have neither a relative or friend who has tubercolosis? What one of us can be sure that we may not some time be afflicted? If we have not that altruistic spirit which will make us care for the health of our neighbors, we certainly have an interest in the prevention of tuberculosis from the standpoint of selfishness. We may not realize it, but the interest in the prevention of this disease is universal.

Science has shown us that every one of these 150,000 people who are lost to our nation annually were infected from some previous case of tuberculosis. Every one died because some previous case scattered infection. It is well for us to stop for a moment and inquire whence come these infecting organisms? They are found in all tuberculous processes and given off in discharges from tuberculous ulcers. The principal source of infection, however, is the sputum of the patient who is suffering from pulmonary consumption. This often contains bacilli in great numbers. This sputum, when expectorated, if allowed to soil the clothing, carpets, or furniture, becomes dangerous; for when it dries, then the bacilli enter the air as dust and may infect those who come in contact with them. Every one who breathes tubercle bacilli into his system does not become infected. It seems that there is a certain predisposition necessary to infection. One man will resist while another under the same circumstances will become infected; but so far as science is able to determine, every one is liable to become infected if the conditions are right at the time he is exposed to the bacilli. Those things which favor infection are such as lower vitality, and make the resisting power of the individual low.

A patient in an advanced stage of pulmonary consumption will cast off in his expectoration several millions of tubercle bacilli in a day. If these bacilli were all virulent and all remained so, the entire race would certainly perish of tuberculosis. With one hundred and fifty thousand people dying annually in the United States from this disease, and most of

*President's address at the first annual meeting of the Southern California Antituberculosis League, Los Angeles, Cal., June 2, 1903.

these expectorating their millions of bacilli daily for months before death, where is the hope of checking the ravages of the disease?

This is certainly a dark picture; but I have only shown you the dark side. If we look at the other side it is radiant with hope. This disease which destroys so many lives and leaves in its wake so much suffering and sorrow is a preventable disease. Ordinary precautions on the part of the afflicted individual will make infection rare; and painstaking care on his part will protect his attendants fully. Perhaps I could impress upon you the difference between care and carelessness in dealing with this disease in no better way than to show you the difference between tuberculosis in the tenement houses, and that in sanatoria. The tenement houses stand for everything that is unclean and insanitary, the sanatoria are examples of hygiene and sanitation carried to the highest point of excellence. The inmates of the former are ignorant of sanitary laws, careless in their personal hygiene, so poor that it would be all but impossible to be careful if they knew how. The inmates of sanatoria, on the other hand, are taught to be cleanly in their habits, live in sanitary quarters and are furnished with everything that is necessary to prevent the spread of infection. As a result, tenement houses are hotbeds of infection, while sanatoria are, from the standpoint of infection, most desirable places in which to live.

In the Fourth and Sixth wards of New York (which include the thickly populated tenement districts), during the years 1894–5, and 6, cases of tuberculosis were reported from 38 per cent. of the dwellings and from twelve houses in this densely populated district, 136 cases were reported to the authorities in eight years previous to 1897. Since only about one-half of the cases were reported, it is probable that twice as many, or about 275 cases, occurred in twelve houses in eight years. That means that those rooms were so thoroughly infected that no one should have occupied them until they had been thoroughly renovated and disinfected. What could better present to your minds the things that are favorable to the spread of infection?

Now let us see how the nurses and attendants who are intimately associated with tuberculous patients in sanatoria fare. In the Brompton Hospital in London there have been treated in the past twenty years fifteen thousand cases of tuberculosis, and yet neither a nurse nor an attendant has become infected. The same freedom from infection on the part of attendants has been enjoyed at Falkenstein in Germany. The Adirondack Cottage Sanatorium and the Winyah in the United States. These examples show plainly that tuberculosis can be prevented. Here we have a prolonged association in an intimate manner of attendants and patients; but because of the sanitary surroundings and the care on the part of those afflicted, there is no danger of spreading the infection.

These examples teach us two important truths: first, experience in the tenement houses shows that tuberculosis is a communicable disease and that it can be communicated from one person to another; second, experience in the sanatoria teaches that tuberculosis is not a contagious disease in the ordinary sense in which that word is used, and that the afflicted and the well may associate intimately together without infection taking place, provided the necessary care is taken. In other words, tuberculosis is preventable.

If tuberculosis is preventable, why is it not prevented? This is a very pertinent question. There can be but one answer: the people have not learned that it is preventable and consequently have not endeavored to learn how to prevent it.

While tuberculosis is found in all lands and all climates; in the country as well as the city; and while it affects the rich as well as the poor, nevertheless it is preëminently a disease of the city and preëminently a disease of the poor. Those who live in poorly lighted, badly ventilated, overcrowded rooms and who subsist on insufficient and badly prepared food are the most prone to infection. It is perhaps not far from the truth to say that 85 per cent. of the people who are suffering from tuberculosis have not the means to place themselves in the proper surroundings for regaining health.

This disease is not only preventable, but it is also curable. At least 50 per cent. of those who are treated early can get well, and with the best of care and treatment a much larger percentage than this. This blessed message of hope is but a mockery as it falls on the ears of the poor; for without help there is no hope for them.

Those of us who are in better circumstances cannot look upon tuberculosis among the poor with indifference. If our love for our fellows does not appeal to us, if the suffering and misery that this disease produces in these wretched homes does not call forth our sympathy, we still cannot shut our eyes to the fact that as long as there is tuberculosis among the poor there will also be tuberculosis among those in better circumstances. Carelessness, ignorance, and poverty are the greatest factors in the spread of tuberculosis, and these we find are working in combination among the under class, preventing any active sanitary measures.

This, in brief, is the statement of facts as we find them. What is to be done? In the first place, public opinion must be aroused. No great movement can go ahead of public opinion. Tuberculosis is so common that the aid of society as a whole is necessary in order to check its ravages. The public must be made to understand that the enormous death rate and the indescribable sufferings which are caused by this disease are unnecessary and that they are caused by a disease that is preventable. The fact of its communicability must also be impressed upon the minds of the people. They must be taught to understand how the disease is communicated from one individual to the other, what things favor this spread of infection and what ones prevent it. While we are teaching these truths, we must be careful not to create an unnecessary alarm. The tuberculous patient should not be treated as a leper. There is no danger in associating with him if he is careful. Humanity should prevent us from heaping additional burdens upon him when science tells us that they are unnecessary. It is our duty to instruct tuberculous individuals how to destroy their sputum, and also to impress upon society that, when this is done, the danger of infection is taken away.

Not only must those who are well be considered, but those who have been so unfortunate as to become afflicted. If 50 per cent. of those who are afflicted can be cured when treated early, as statistics show, then the public conscience should be aroused to its duty to see that those who are afflicted are given the opportunity to get well. Then, too, if one-half of those wo are ill can be saved from reaching that stage in which they are giving off so many bacilli a day, it can be readily seen that this would be an important move in the prevention of the spread of the disease. Every case that is prevented from reaching the advanced stage, and every case which has already reached it that is cared for, as is done in hospitals, is a step in the ultimate eradication of the disease.

In order to prevent the spread of tuberculosis it is not only necessary to care for the afflicted; to educate them how to care for their sputum; and how not to infect their surroundings; but also to educate the well so that they may withstand infection. The danger of spreading tuberculosis is not all on the part of the afflicted. On the contrary, people are doing those things every day which lower vitality and make infection easy. The pernicious habit of living in poorly ventilated and badly lighted apartments which is so common in civilized lands is accountable for much of the tuberculosis among us. I do not mean that living in such quarters alone will produce tuberculosis, but that the evil effect of such a life makes the organs of respiration weak and unable to resist the germs of infection which are taken in, and also renders the general resistance low, so that when the germs have found lodgment they have little to oppose their progress. So, while we are teaching the people how to prevent the spread of the germs that cause tuberculosis, let us not forget that it is equally important to teach the necessity of living natural lives with a generous supply of sunlight in our homes and surrounded by fresh air day and night. The principles of hygiene and sanitation must be made to be the guides of our lives.

How are these truths to be taught? How is public sentiment to be aroused? Only through organization. There must be some central body whose business it is to teach the people how to prevent tuberculosis. It must be the duty of this organization to teach the people that this disease is communicable, that it is preventable, and that it is curable; to educate public sentiment and guide it in the right channels.

Here let me quote from my address on the occasion of the first meeting of the Board of Directors of this organization:

"The work of the Southern California Antituberculosis League should be carried out along several lines. In the first place, we should educate the people to the fact that tuberculosis is communicable. We should teach them just where the danger lies, and that if the bacillus-bearing discharges, of which the sputum is the chief, and in most cases the only, one, are destroyed, there is no danger from the tuberculous individual. While we must insist on the enforcement of sanitary laws, yet we must avoid creating in the minds of the people an unnecessary fear which will work undue hardships on those afflicted. Nowhere can it be said with greater justice that "a little learning maketh mad," for those who have learned that tuberculosis is a communicable disease, and have learned nothing more, have become frightened, and are associating, in their minds, tuberculosis with such diseases as smallpox. We must emphasize with equal, if not greater, care that tuberculosis is preventable. We must furthermore teach them how to prevent it; give full and explicit directions for the afflicted, and also for those who must care for him. The necessity of sunlight and fresh air must be emphasized,

"Sanitary laws relative to the prevention of infection, such as those forbidding expectoration in public places, providing for the notification of tuberculous cases and the disinfection of rooms occupied by tuberculous individuals before being reoccupied, should be passed. In order to facilitate and encourage early diagnosis in the cases among the poor, free examination of sputum should be made of those who are too poor to pay for the same. Laws regulating the height of buildings, the height of ceilings, the ventilation of workshops and tenement houses, preventing the construction of insanitary dwellings and overcrowding, would do much to prevent that lower vitality which facilitates infection and would offer less opportunity for the bacilli to thrive.

"Lest I be misunderstood, I would like to offer a word on the subject of notification, before passing. There is objection raised to this on the part of some, believing that it would work as a quarantine. Not so. It is only intended that the case be reported, that the health officer may see that precautions are carried out. No one but the attending physician and the health officer need know that the individual is tuberculous. It should work in favor of the afflicted instead of against him.

"Another important field of work for our league is found in caring for the afflicted poor. This is a necessary measure from the standpoint of prevention and desirable from the standpoint of the humanitarian. As long as the poverty-stricken tuberculous individual is compelled to care for himself, he will be forced to occupy insanitary quarters, and will scatter infection about him, either because of ignorance or because of a spirit of apathy. Since each patient, on an average, infects about one new one, and each careless one may infect several, it can be plainly seen that the care of the helpless poor bears a very important relation to the problem of prevention of tuberculosis, and since hospital facilities are provided for those suffering from other diseases, it is but just that they should be provided for these.

"The Antituberculosis League could perform for the tuberculous poor an act of mercy, render society a noble service, and do itself a great honor, if through its efforts there should be established in our midst a system of dispensaries in the cities where those afflicted could come for advice and those who suspect the disease could be examined while they are in a curable stage; and further, if through its agency there should be provided sanatorium facilities for those who are curable and hospitals for those in the advanced stage.

"Such is the work that has been done by organizations of similar aim. Such is the work that, I hope, will be accomplished by ours. We have to work slowly, for we can not go faster than public opinion, but by the distribution of carefully written pamphlets, by the delivery of thoughtfully prepared lectures, and by the judicious use of the public press I believe that it is possible to secure a hearty coöperation on the part of the people."

---

**A Case of Malta Fever in Washington, D. C.**—W. B. Banister reports a case first seen in January, 1903. The patient had been in the Philippines, where he had suffered from fever which was believed to be malarial. For two months the author had him under observation, and found that his disease presented the clinical features of Malta fever—presenting a series of febrile attacks, each lasting a week or more, followed by apyrexial or relatively apyrexial periods of several days' or weeks' duration. Rheumatic-like swellings of joints were absent in this case, but are a frequent complication, as are diaphoresis and anæmia. Serum reaction with the micrococcus melitensis was decided, as evidenced by marked agglutination. There is no specific for Malta fever, and there is no drug known to influence its course. Excessive pyrexia should be reduced with cold baths or the wet pack; constipation relieved, and during a pyrexial period liquid diet should be given. Codeine controls the cough when troublesome, and secures sleep without increasing the tendency to constipation. The debility should be combated with strychnine and tonics. The mortality of Malta fever is low, only 2 per cent. The most serious effects are the debility and anæmia which it entails.—*Washington Medical Annals.*

## EXTENSIVE BRAIN LOSS WITHOUT IMPAIRMENT OF INTELLECTUAL FACULTIES.

By WALTER KEATE, M.D.,
NACOZARI, SONORA, MEX.

The following are the details of an accident which occurred near here on May 18, 1903:

John G., a miner, aged forty years, was preparing to spring a hole with dynamite in which he had 6½ sticks of giant powder inserted. While he was arranging them they accidently exploded while his face was directly over the hole. I reached him two hours after the explosion. His pulse was 30 per minute, and very weak. The eyes were blown out, the skin and muscles and forehead were partly blown off, with the anterior portion of the skull cap turned back over the parietal bones. The orbital plate of the frontal bone, forming the roof of the orbit, was blown into the brain, and the brains exuded through the opening into the cheek. There was a hole in the frontal bone about the size of a silver ten-cent piece. The hole was located at about

the center of the frontal bone, through which the brains exuded.

The membranes of the brain—dura mater, arachnoid, and pia mater—were badly lacerated, as were also the frontal lobes of the brain. The end of the nose was badly cut, the face and lips were badly burned with powder and literally filled with small rocks and dirt.

After trephining to make the opening a little larger, and to smoothe the ragged edges, I removed from the brain twenty small stones and several pieces of bone, together with considerable dirt Most of the foreign bodies were located at a point corresponding to the anterior fontanelle, deeply buried in the brain. A large piece of bone corresponding to the roof of the orbit was extracted from the brain through the opening in the forehead.

The amount of cerebral matter which came away weighed one ounce. It may sound incredible, but it is a fact that the patient has never for one moment been unconscious. His mind has been perfectly clear, and he can readily recognize his friends when they speak to him. He answers all questions intelligently, and describes accurately the details of the accident. He has never complained of pain, and says the anterior portion of the head feels paralyzed. His appetite is, and always has been, fairly good.

The first two weeks his temperature ranged between 100° and 103°, but the last two weeks it has been practically normal.

He has been able to get up every day since the accident, and locomotion is good. It has been just a month to-day, and as I write this article the patient is sitting in a rocker on the porch in the fresh air, chewing tobacco.

Both eyes are completely destroyed. The picture of the patient gives but a faint idea of how he really looks.

## ECZEMA CURED BY MEASLES.

By G. W. SQUIRES, M.D.,
EAST AVON, N. Y.

Mark D., aged eighteen months, naturally born and healthy at birth, with the age of ten months became sadly afflicted with facial eczema. Except for some constipation and the eruption the child seemed perfectly healthy. Various kinds of medicines within and ointments and washes without were without effect. The exudation of serum was such that at night the pillow on which the child lay would be wet, and often when the crusts formed and cracked the child's hands, sheets, and pillows would be stained with blood. At this juncture, when the parents were despairing of a cure, an older brother contracted measles at school, came home, and had a hard attack. Much alarm was felt lest the baby should contract the measles and, with his already bad skin eruption, die. The baby, in due time after exposure, got very dangerously sick with the measles. He had fever and delirium and the skin was as red as a boiled lobster. In due time convalescence set in, and what was the surprise of physician and friends to see the eczema melt away like snow in the spring time, and every trace of the former eruption disappear, leaving the skin as soft and clean as a baby's can be. Now, after a year, there has never been the slightest symptom of a return of the facial eczema.

**Thrombosis of the Femoral Veins Following Aseptic Laparotomy.**—E. R. Secard reports a case of operation for bilateral oblique inguinal hernia, which was carried out under the strictest aseptic precautions. Convalescence was uneventful, and the stitches were removed on the tenth day, primary union having occurred in the most satisfactory manner. Pain in the left groin, popliteal space and calf of the left leg began on the twelfth day, and a condition of extensive venous thrombosis set in. It ran a more or less benign course. It occurred on the side where the less extensive operation had been done, where there was less handling of the parts and less hemorrhage, but where a truss had been more or less constantly worn for twelve years. A study of this and other cases leads the author to the conclusions: (1) That no one etiological factor is alone responsible for the occurrence of this complication; (2) that the rate of infection in otherwise non-infective cases does not appear to be an important one; (3) conditions of sudden decrease of pressure dependent on the operation probably have a causative influence; (4) treatment should be prophylactic, as by avoidance of unnecessary traumatism, or hemorrhage, or of suddenly decreased tension, as by having the wound area well supported by firmly applied dressings. (5) So far as the author is aware there has been no mortality in the reported cases, but the occurrence of pulmonary embolism in a certain proportion warns us that this termination is not an impossible one.—*The Montreal Medical Journal.*

## THE STATE LAW AGAINST FAITH CURE.

THE vexed question regarding the legal status of the so-called Faith Cure in this State has at last been definitely settled by a recent decision of the Court of Appeals in the case of J. Luther Pierson of White Plains, N. Y., whose child died of bronchopneumonia while under the care of a Christian Scientist. He was convicted by a jury for intentionally failing to provide medical aid for the patient and sentenced to five hundred days in jail with a fine of five hundred dollars. The Appellate Court reversed the judgment of conviction on alleged errors of law. The majority of that court entertained the view that the indictment failed to charge a criminal offence for the reason that it did not contain an allegation that the case was one in which a licensed physician ought to have been called. The Court of Appeals duly reversed the decision of the Appellate Division and the final judgment of conviction now stands. The interest in the case for the medical profession, not only in this but in other States, rests upon the argument in support of the decision in question. Judge Haight writes the following opinion in which the other judges concur:

"Section 288 of the Penal Code, so far as is material upon the question under consideration, provides as follows:—'A person who (1) wilfully omits without lawful excuse to perform a duty, by law imposed upon him, to furnish food, clothing, shelter, or medical attendance to a minor . . . or (4) neglects, refuses, or omits to comply with any provisions of this section . . . is guilty of a misdemeanor.'

"It would seem that the legislative intent in adopting this provision of the code is reasonably clear, although possibly more precise language could have been employed. It contemplates that there are persons upon whom the law casts a duty of caring for minors, but it does not specify the persons. They are, however, those upon whom the duty is 'by law imposed.'

"We quite agree that the code does not contemplate the necessity of calling a physician for every trifling complaint with which the child may be afflicted, which in most instances may be overcome by the ordinary household nursing by members of the family; that a reasonable amount of discretion is vested in parents, charged with the duty of maintaining and bringing up infant children; and that the standard is at what time would an ordinary prudent person, solicitous for the welfare of his child and anxious to promote its recovery, deem it necessary to call in the services of a physician."

In defining what is meant in law by the term "medical attendance" the learned judge thus very pertinently says:

"The Legislature first limits the right to practise medicine to those who have been licensed and registered, or have received a diploma from some incorporated college conferring upon them the degree of Doctor of Medicine; and then the following year it enacts the provision of the Penal Code, under consideration, in which it requires the procurement of medical attendance under the circumstances to which we have called attention. We think, therefore, that the medical attendance required by the code is the authorized medical attendance prescribed by the statute, and this view is strengthened from the fact that the third subdivision of this section of the code requires nurses to report certain conditions of infants under two weeks of age 'to a legally qualified practitioner of medicine of the city, town or place where such child is being cared for,' thus particularly specifying the kind of practitioner recognized by the statute as a medical attendant."

Regarding the purely religious aspect of the question, the court does not feel itself competent to give an opinion, as from a purely legal point of view it is manifestly incompetent to decide on the soundness of any purely doctrinal faith. From a strictly scientific view, however, the line must be drawn between mere faith or belief and practice endangering life. Thus trusting in faith cure in the case of actual disease demanding active medical treatment is obviously a species of criminal neglect deserving legal punishment in the interest of public welfare.

## MIXED INFECTIONS AFTER VACCINATION.

No. 355 of the *Sammlung klinischer Vorträge* contains the experience of Dr. Leonhard Voigt, Director of Vaccination in Hamburg since 1874. Since that date 400,000 persons have been vaccinated at his institution, and 600,000 within the Hamburg territory, and since 1884 589,586 children have been vaccinated. Voigt has made a careful study of all anomalies following vaccination, and since 1890 all such cases, and the causes of all deaths occurring shortly after vaccination, have been reported to him.

Only such records can, Voigt rightly remarks, refute the objections raised by the opponents of vaccination. The following are all the mixed infections observed: *Suppuration of pustule:* 35 cases (1 death). *Suppuration of axillary glands:* 12 cases. *Erysipelas:* 13 cases; as this disease develops within twenty-four hours of its inoculation, the time of its appearance determines which cases are chargeable to the vaccination, and 10 of the cases (including the one fatal case) were not so chargeable. Moreover, the other 3 cases occurred so late and healed so rapidly that they may fairly be conjectured to have been not erysipelas but an unusually violent local vaccine action, which can give rise to a dusky red around the pustule and swelling up to the shoulder and down into the forearm. *Phlegmon:* 4 cases (2 deaths), 2 to 4 weeks after (and independent of) vaccination. *Eruptions:* As a rule no pure vaccinal eruptions occur; with sensitive skins, however, a fugitive redness, often resembling scarlatina, German measles, or measles, develops. Many times

an urticarial, rarely a pustular, stage is reached. Among 354,000 vaccinations, 1893-1902, 293 cases worthy of mention were seen, 85 of them in which eczematous eruptions had pre-existed, under which condition the vaccinal irritation many times awakens renewed activity during the vaccinal week. The other 208 cases gave no evidence or history of precedent rashes. As, however, they occurred sporadically among a number vaccinated from the same stock of virus who remained free, they evidently were not due to any eczematogenous factor in the vaccine. *Urticaria:* The same may be said of these 32 cases, several of them only revivifications of a precedent eruption.

Secondary pustules, due to self-infection by scratching, are important only when implanted at the meatus urinarius, on the eye, or on eczematous patches (especially crusta lactea, in which the surface rapidly becomes covered with confluent pustules and life may be endangered). Six such infections (of non-vaccinated persons) were seen. The itching of blepharitis favors secondary infection by scratching, and the secondary pustules are liable at least to cause the loss of some eyelashes. Involvement of the eye may lead to a cloudy corneal scar, or may fan up an existing scrofulous inflammation. *Eye inflammations:* 30 were seen, many of them clearly exacerbations of precedent eczemas, or the fortuitous appearance of a sty. Once croupous (but non-vaccinal) inflammation existed. The remaining cases showed inoculation usually at the outer canthus, 6 times on the globe. Twice former scrofulous inflammations lighted up and continued some months after vaccination. *Impetigo:* When vaccinal impetigo appears it occurs not sporadically but over the group inoculated with the infected lymph. Then the pustule develops into strongly itching vesicles which burst early and result through self-infection in an irregularly distributed, very contagious eruption. One such instance occurred in 1878, when animal lymph had not yet acquired its present exclusive place. As a rule, however, impetigo develops because a small patch pre-existed. Besides these cases, 85 cases were seen during or shortly after the vaccinal week, among 590,000 vaccinations. A non-vaccinal cause was evident in 50, the pustule was impetiginous in only 3 (that is, 26 of the 29 fairly made out post-vaccinal cases were not vaccinal in origin), which, moreover, occurred scattered among a number of vaccinations.

In *ichthyosis* vaccination runs a normal course. With *psoriasis* it is otherwise, 2 cases among 12-year old school children having shown transitory increase in the psoriasis. Spite of all vaccinatory precautions, every year some cases of *measles* and *varicella* coincide with the vaccinal week, their general distribution and long incubation period favoring such concurrence. In general, the measles and vaccination run their normal course, the pustule appearing to heal somewhat more slowly. The coincidence of the two fevers involved 2 deaths, and a third occurred from pneumonia the twelfth day after vaccination and the ninth of the measles. Much more frequent is the concurrence of varicella. Only 1 death was observed, from convulsions the sixteenth day after vaccination and the tenth of the varicella.

*Scarlatina* rarely concurs: five cases, with 1 death in a one-year-old, who the second day after vaccination developed varicella, and the fifth day scarlatina, and on the twenty-fourth day after vaccination died of bilateral middle-ear disease, with brain symptoms. *Diphtheritic inflammation of the cervical glands:* two children of one family died, the three others simultaneously attacked recovering; a fourth case, with aphthous stomatitis, impetigo, measles, diphtheria and staphylococcus and streptococcus infections, died. *Aphthous stomatitis* not rarely coincides with the vaccinal week; both diseases run their normal courses. *Mumps:* 4 cases, suppuration of the glands occurring once; also once mumps, impetigo, and pertussis, pronounced by a "nature doctor," vaccinal syphilis. *Syphilis, tuberculosis:* No instance of such infections observed. *Brain disease:* The past twelve years 4 children died (on the sixth, sixteenth and twenty-seventh days after vaccination). While one will not err in thinking that here vaccination influenced unfavorably the precedent disease (tuberculous inflammation), it would be erroneous to believe the former the cause, inasmuch as the post-vaccinal weeks show only one-ninth as many children dying from such inflammation as the expectation for those ages would justify us in looking for. Swelling of two phalanges of the finger, and swelling of the diaphyses of both tibiæ: each one case, resembling tuberculous bone diseases; the latter cured after eight months, the outcome in the former not stated. *Tetanus:* 1 case, four days after vaccination, in a child who some days before vaccination had fallen on his head on to the floor, but without external wound; the known minimal incubation period being 6 days, the cause could not be accepted as vaccinal.

The author then shows by a somewhat extended calculation, that not only is it not true that the three weeks following vaccination are weeks of exceptional danger, but that the exact reverse is the case, namely, that those weeks constitute a period in which the death rate from such diseases as bronchitis, pneumonia, diphtheria, measles, scarlatina, cholera, convulsions, brain inflammation and diarrhœa, falls to one-seventh to one-twentieth of that to be expected from the known mortality for the given ages. Thus for pneumonia and diphtheria there should have died 51.6 and 20.8 respectively, whereas actually only 7 and 3 died; and similarly, whereas for diarrhœa a mortality of 200 should have occurred, only 10 died. It would thus seem that the vaccination process prevents, or possibly only delays, the development of other zymotic diseases. Among other conclusions Voigt says that from his experience he must doubt the production by vaccination in previously free persons of eruptions which long outlast the vaccinal period, and that the foregoing associated diseases are mostly not to be regarded as consequences of the vaccination, but as mixed infections in the vaccinated, which occurring so extremely rarely are merely unfortunate intercurrent accidents which for the most part can be prevented by greater care in the household.

---

**College of Physicians of Philadelphia.**—At a stated meeting, held October 7, Dr. Chas. W. Burr presented a portrait of the late Dr. Frederick A. Packard.

### Camp Life for the Insane.

Out-of-door life for the tuberculous insane, since Dr. Macdonald's successful experiments in thus treating that class of patients, has been everywhere favorably referred to. The New York *Sun*, October 4, contains a description of an experiment upon similar lines, which was carried out by Dr. Eugene Howard, Superintendent of the Rochester State Hospital, at the direction of the State Commission in Lunacy, the patients in this instance being the ordinary insane. A summer camp was formed on the shore of Lake Ontario, eight miles from Rochester. The site covered four acres of land, on which stood a large cottage and barns. Tents were erected and accommodation provided for about thirty patients, who were sent thither under the care of a corps of nurses. The patients chosen for the experiment were those who were harmless and partly recovered, and no patient was allowed to remain longer than a week or two, so that the largest number possible might receive the benefit of the change. According to the article in the *Sun*, "during the summer 72 men and 128 women patients were sent to the camp and their progress was carefully noted. So successful has the experiment been that Dr. Howard, in his annual report to the State Commission, which he is now compiling, will recommend the purchase of a farm of sixty acres adjoining the present four-acre camp. He will recommend the erection of several cottages and a more complete equipment, so that the experiment can have a more thorough trial."

The treatment of harmless lunatics, in permitting them to enjoy the health-giving properties of a life in the open air, together with the distraction and pleasure afforded by a change of scene and by a different manner of living, must have a beneficial effect upon their physical condition, and should also act favorably upon their mental state.

### Colonies for Consumptives.

It is generally allowed that occupation of some kind is beneficial to those suffering from certain diseases. Indeed, when possible, it is always better that sick persons should be employed, so that they should not be continually brooding over their condition. This statement applies, with perhaps as much force to consumptives as to the victims of any other malady, as, although the phthisical patient is frequently unconscious of the gravity of his case, yet in a very large number of instances, he worries and exaggerates the seriousness of his affection. At any rate the fact cannot be gainsaid, that the consumptive on the whole is much more likely to improve in health if employed. For the consumptive of the working class, it would seem that an industrial colony could not but be a great boon, while, if not entirely self-supporting, it might at least be made to produce a portion of the cost of maintenance.

According to the *Medical Magazine*, the undertaking of such a project has been strongly advocated by a writer in the *Newcastle Chronicle* of a recent date. The writer, who is undoubtedly a medical man, points out that by the establishment of industrial colonies, the advantages of sanatoria may be procured, and in addition, the patients will become once more wage-earners. There would be no rivalry between the two institutions, for the one would be supplementary or complementary to the other. In these "colonies," workers and non-workers alike could live, although it would be better that they should be distinct and separate. The inhabitants of the "industrial colonies" would work and live under practically the same conditions of medical supervision and advice, and the knowleged that they were wholly or in part earning their livelihood would be advantageous to their morale. The enforced idleness of sanatorium life is irksome after a time to most patients, and the constant self-nursing which is generally their sole occupation has certain quite obvious disadvantages.

The writer states that as yet there is not a single colony for consumptives. He is probably thoroughly acquainted with his subject, and it would seem that he is certainly correct when he says that "all interested in the sanatoria movement fully recognize the fact that colonies are desirable adjuncts to them." Many other details in reference to the scheme are mentioned, which it is not necessary to write of here, but the main idea of establishing colonies and industrial colonies for consumptives seems to be a good one and might commend itself as such to the many persons in this country who are deeply interested in the welfare of the sufferers from this disease.

### The Effect of Lecithin upon Growth.

The *American Journal of Physiology* for September 1, 1903, contains a study by Shinkishi Hatai, of the University of Chicago upon the effect of lecithin on the growth of the white rats. In 1895 Danielewsky found that frogs' eggs gained three times as much in weight when incubated in water containing lecithin in the proportion of 1-1500, as when incubated in ordinary water, and since then other observers have shown that lecithin exercises a similar effect upon the growth of higher animals. Thus, Desgrey and Zaky saw the same effect in guinea-pigs, and they advanced the opinion that the action of lecithin is that of a stimulating agent. Hatai studied the effect produced by the continuous daily administration, both by injection of 5 milligrams, and by the feeding of 10 milligrams, control animals being used in both series and every case under precisely the same conditions. Omitting the details of the experiments, the conclusions of the author may be cited. They are: White rats receiving lecithin, either by injection or feeding, gain in body weight more rapidly than do the control rats, the gain in the experimented rats being on the average 60 per cent. greater than that observed in the control rats; the weight of the central nervous system relative to that of the whole body, is mal; and the nervous system contains the same relative proportion of solids and water as in the controls, which affords another indication of the normal character of the growth. The normal character of the growth in the peripheral nerves is shown by the same relative area of the cross section of the axis cylinder of the nerve, as compared with the area of its sheath, in both the experimented and control rats; and that his results confirm strongly the claims of former investigators that lecithin is a stimulant agent for normal growth. One other observation was particularly interesting, namely, that the rats to which lecithin was administered showed a greater power of resistance to unfavorable influences; for example, their growth was more uniform, that of the control rats showing a much more variable growth curve in connection with various deterrent factors, such as variability of temperature, etc. On the whole, it would seem then that lecithin may some day come to have a standing in practical therapeutics.

### Goat Cure for Smallpox.

Superstition dies hard, and some quaint beliefs are still held to in rural districts in all parts of the world. Of course an old country as England is, is not exempt from this human failing, and in some

parts of that land the credulity of some of the peasantry is almost pathetic. The Eastern counties of England are particularly distinguished for the persistency with which the inhabitants adhere to the lore of their fathers, but the report that the *London Daily Express* gives as to happenings in Cambridge recently, almost passes credence. Cambridge, the seat of one of the most renowned universities of the world, is undergoing an epidemic of smallpox. The diagnosis of the disease has presented some difficulties, and many well-known physicians have given their opinion on the matter, and the most modern methods have been put into force in order to stamp out the disease. There are, however, within Cambridge itself, despite its colleges and learned men, a goodly number of citizens who have no faith in "new-fangled views on medicine," and who follow with admirable doggedness the old-time methods of treatment handed down to them by their forefathers. Thus the Cambridge correspondent of the *Daily Express* writes, "It is practically a set-down rule in the Newmarket Road district of Cambridge, known as Barnwell, that where a goat goes smallpox will not follow, and almost every householder is fully in sympathy with the idea. A good samaritan of the locality keeps a goat. After daily work is completed in the evening, one of the men takes the goat out on a chain, and, followed by a large congregation of children, goes from house to house until both the goat and man are tired. When in a house the goat is treated with great kindness—in fact, it is regarded almost as a doctor. It is led into every room, and after circling it several times, passes on to the next, and the house is henceforward regarded as clean, and its occupants continue their duties in the fixed belief that they will never have smallpox."

## News of the Week.

**Increase in Contagious Diseases in Philadelphia.**—For the week ended October 10 there were reported to the Philadelphia Bureau of Health 82 cases of diphtheria, with 9 deaths; 84 cases of scarlet fever, with 2 deaths; 78 cases of typhoid fever, with 9 deaths; and 11 cases of smallpox, with 3 deaths. The total number of deaths for the week was 395, as compared with 400 for the preceding week and with 352 for the corresponding week of the previous year.

**The American Academy of Railway Surgeons.**—At the tenth annual meeting of this society, held in Chicago, on October 1 and 2, 1903, under the presidency of Dr. L. Sexton of New Orleans, the following officers were elected: *President*, Dr. Samuel C. Plummer of Chicago; *Vice-Presidents*, Drs. A. L. Wright of Carroll, Iowa, and W. U. Cole of Columbus, Ohio; *Secretary and Treasurer*, Dr. Thomas B. Lacey of Council Bluffs, Iowa; *Assistant Secretary*, Dr. H. B. Jennings of Council Bluffs, Iowa; *Editor*, Dr. D. S. Fairchild of Des Moines, Iowa. The next annual meeting will be held in Chicago in the autumn of 1904.

**The Oregon State Medical Society.**—At the annual meeting of this society, held last month, the following officers were elected: *President*, Dr. W. T. Williamson of Salem; *Vice-Presidents*, Drs. G. W. Tape of Hot Lake, E. E. Ferguson of The Dalles, and Mae H. Cardwell of Portland; *Secretary*, Dr. L. H. Hamilton of Portland; *Treasurer*, Dr. Jessie McGavin of Portland; *Councillors*, Drs. S. E. Josephi, W. F. Amos, W. J. May, J. S. Fulton, George F. Wilson, W. T. Williamson, William House, C. S. White, R. C. Coffey, and S. T. Linklater; *Delegate to the American Medical Association*, Dr. J. C. Smith of Pendleton; *Alternate*, Dr. K. A. J. Mackenzie of Portland.

**The Board of Police Surgeons.**—Police Commissioner Greene has recently taken away the power of electing their own officers from the police surgeons and has vested the power of appointment and removal at will in the Commissioner himself. Soon after the change in rule was announced the commissioner appointed Dr. E. T. T. Marsh chief surgeon and president of the Board of Police Surgeons and Dr. Henry P. de Forest secretary.

**A Plague Congress.**—An International Sanitary Congress for the Adoption of Means of Defense against Cholera and the Plague opened in Paris on October 10. Representatives of twenty-five powers were present, including Surgeon Anderson, United States Navy, Medical Inspector of the United States European station; Colonel Gorgas, formerly Chief Sanitary Officer of the United States at Havana, and Dr. Giddings, representing the United States. Foreign Minister Delcasse, in the opening address, pointed out the necessity for international coöperation in resisting the spread of epidemics.

**A New Intoxicant.**—Major Jennings writes in the *Journal of the Royal Army Medical Corps* for October that during the South African campaign the British soldiers discovered a new and extraordinary form of intoxication. Ingenious Tommy Atkins found that when deprived of gin and beer he could get all the excitement he wanted by eating the cordite used to charge cartridges. This form of smokeless powder is composed of nitroglycerin, guncotton, and vaselin, and comes in the shape of long cords (whence its name), similar in appearance to vermicelli. Major Jennings, on learning that the men had been eating cordite, made experiments himself. On sucking a strand he found it sweet, pleasant, and pungent, but the indulgence usually results in a headache which lasts for twenty-four hours. Dissolved in tea it produces almost immediate exhilaration, "inciting almost demoniacal actions," followed by a heavy sleep and stupor of from five to twelve hours, according to the amount taken. If beer is taken after the cordite tea it produces the worst effects, exciting a quarrelsome and destructive mania and producing the most rapid intoxication. From his study of eight cases of cordite addiction the writer concludes that the symptoms and effects produced by the poison are sufficiently forcible and unpleasant to prevent any but the most depraved resorting to it as either a cerebral stimulant or sedative.

**Tuberculosis Sanatoria in Madeira.**—The Portuguese Government has granted a concession to Prince Frederick Charles v. Hohenlohe for the erection of sanatoria for the treatment of tuberculosis in the island of Madeira. These establishments will be exempt from taxation, and no customs duties will be levied on imported material employed in their construction. In return, the Government reserves for the State the right to 20 per cent. of the beds in the sanatorium for the poorer classes. The Prince, accompanied by Drs. Frankel and Pannwitz and a physician appointed by the Portuguese Government, is now in Madeira for the purpose of selecting sites in the central part of the island for two large sanatoria for patients and a hotel for people accompanying the invalids. The buildings will be similar to those in German watering-places. The buildings will be begun as soon as the report on the sites decided upon has received the approval of the Board of Health.

**The New Bellevue.**—Work on the new Bellevue Hospital is to be begun at once. The Aldermen

recently sanctioned the closing of Twenty-eighth street so that the block to the north of the present site can be used for the enlargement of the hospital. The condemnation of this block has already been authorized. The Board of Trustees has requested the War Department to permit the extension of the pier bulkhead 200 feet into the East River. This will give the new hospital site a river frontage of 710 feet.

**The Report of the Surgeon-General of the Army.**—In the report of Surgeon-General R. M. O'Reilly for the year ending June 30, an interesting comparison is made between the three races—Caucasian, African, and Malay—represented in the army. "The enrolment of about 5,000 native Filipino scouts," he says, "having added a new racial element to the army, it becomes a matter of much interest to study the comparative effects of disease on them and on our white and colored troops. For the whole army, at home and abroad, during the year 1902, the white troops showed an admission rate of 1706.33 a thousand and a death rate of 14.40. The negro troops had 1897.74 admissions and 24.11 deaths a thousand, and the Malay scouts 1707.21 admissions a thousand and 24.04 deaths. The white race, therefore, gave the lowest figures in sickness and much the lowest mortality. The black race led in both, although the Malay closely approached it in death rate. The freedom of the Filipino from the vice of drunkenness is strikingly shown when we find that out of 5,000 men only three individuals were treated for alcoholism in one year, and that while white soldiers were admitted to sick report on account of misconduct in the use of alcohol at the rate of 24.78 per thousand, and colored troops at the rate of 11.70, the Malay scouts showed the extremely small admission rate of 0.62 per thousand." The report shows an increase in the death rate of the entire army from 13.94 per thousand in the year ending June 30, 1902, to 15.49 per thousand in the year ending June 30, 1903. This increase is attributed to cholera, which caused 3.54 deaths a thousand. A slight improvement appears in the admission rate for disease and injury, which declines from 1791.59 a thousand to 1716.51. A slight diminution of insanity occurred in the army during 1902. There were 138 new cases, equivalent to the admission rate of 1.71 per 1,000, which is almost identical with the rate for the decade 1891 to 1900. Additional testimony regarding the increase in vice which the closing of the canteens has entailed is given in the following words: "The steadily increasing prevalence of venereal diseases is the most discouraging feature in the sick report of the army. During 1902, 13,000 admissions were from this cause, equivalent to a rate of 160.94 per thousand. Admissions to sick report from alcoholism in 1902 were slightly in excess of the number (including volunteers) for 1901. A total number of 1,830 cases, equivalent to 22.65 per thousand in strength, occurred. It is impossible not to attribute a large part of the steadily increasing venereal diseases of the army to the loss of the canteen, where the soldier, if he so desired, could get his beer throughout the month, but was not subjected to the temptations to intemperance and vice now attendant on the expenditure of a full month's pay at the low resorts infesting the outskirts of our military reservations."

**A Vaccination Complication.**—The high school girls in an Indiana town have risen in revolt against a recently enacted city ordinance, which declares that those not previously vaccinated must submit to the operation at the hands of the doctors in the employ of the Board of Health. They refuse to be vaccinated on the arm and have told the principal of their school that the medical students, as they term the young physicians sent by the Board of Health, shall not vaccinate them on the leg.

**Koch's Work in South Africa Criticised.**—Comment is made in a recent issue of the *British Medical Journal* upon an article in the *Natal Witness*, from which it appears that the observations which Koch has recorded upon the cattle disease in Southern Rhodesia have not escaped hostile criticism in South Africa. The article in question, entitled "The Inconsistency of Dr. Koch," contains a vigorous protest against the discrepancies and confusion in which, it is alleged, Dr. Koch has involved the whole subject of red-water fever in cattle. According to the writer, the German professor commits the blunder of identifying both Rhodesian fever and Texas, or red-water fever, with the cattle fever of the East Coast of Africa, whilst at the same time maintaining that the two former fevers are not identical with one another. In support of this charge extracts are quoted from Dr. Koch's reports of 1897, when he was commissioned to investigate the cattle fever on the East Coast of Africa, and are compared with quotations from his report, dated May 23 of the present year, on the cattle disease in Southern Rhodesia. It certainly appears that Koch has not succeeded in reconciling his various statements in a very clear or convincing fashion. It is only fair to add, however, that the writer in the *Natal Witness* is evidently prejudiced against the Berlin professor, and it is possible the latter may be able, when his time to be heard comes, to vindicate his position against the charge of scientific inaccuracy.

**A Sanatorium Physician Shot.**—The husband of a woman who recently escaped from a sanatorium on Long Island, where she was under treatment for a nervous trouble, shot the owner of the institution. Upon learning of his wife's disappearance the man became greatly excited, and breaking in upon the physician in his study, wildly fired a revolver several times, one of the shots taking effect in the doctor's thigh and inflicting a serious wound.

**Death of Dr. David Franklin.**—Dr. David Franklin of this city died on October 6, after an operation for appendicitis. His wife died three weeks ago. During the course of her illness he was seized with appendicitis, but deferred operation until the recovery of his wife, which both confidently expected. After her death he submitted to operation but it was then too late. He was born in this city and was graduated from the New York University Medical School in the class of 1878. After serving a term as interne in Bellevue Hospital he went to California, but after a short stay returned to this city and entered upon active practice. He was president of the Harlem Medical Society, and was also a member of the Society of Alumni of Bellevue Hospital. He was visiting physician to the Hebrew Ophan Asylum.

The following resolution was unanimously passed at a meeting of the Harlem Medical Association, held October 7, 1903:

"*Whereas*, By the inscrutable ways of a Divine Providence, we have lost in the death of Dr. David Franklin, one of our most loyal, conscientious, and faithful members, for many years the treasurer and a trustee, and at one time president, of the Harlem Medical Association, Therefore be it

"*Resolved*, That we enter upon our records this minute of our lasting regret at his untimely death and our deep appreciation of the many traits of his character which endeared him to all.

"Dr. Franklin was known to us as a model of quiet patience, perseverance and determination of character, and as one of nature's noblemen; a skilful physician, a cheerful councillor, and a loyal friend.

As a physician he was thorough, clear-headed, and scientific, studying each and every case intrusted to his care with the patient minuteness of detail so requisite, and his large and successful practice bears every evidence of the success that follows such painstaking attention. His faithful service as physician to the Orphan Asylum for twenty years abundantly shows his unswerving attention to duty. Not only were his services eagerly sought by those suffering, but he became endeared to those who knew him, and his counsel was often asked and as eagerly accepted, as it was cheerfully given. As a friend he was all that the name implies, ready to respond to any call made upon him, self-denying and self-effacing, tried, faithful, and true. Although taken from those who loved him at the very zenith of his career, when there was every reason to believe that there was a future of happiness and fame awaiting him, his all too short life brings to us all a lesson we may profit by. We shall ever bear him in fond remembrance, and place this record of his manly, loyal, consistent, gentle, and true character upon our records, as they are engraved in our memories."

EMIL MAYER, RICHARD VAN SANTVOORD, MONTROSE R. RICHARD, Committee.

**Obituary Notes.**—Dr. WILLIAM D. WOOD died at his home in Jamaica, Queens Borough, New York, on October 4, at the age of eighty-three years. He was born in Lincolnshire, England, but came to this country early in life, and obtained his medical degree from the Castleton Medical School, Vermont, in 1854. During the Civil War he was a surgeon in the Eighty-ninth New York Volunteers. For the past ten years he had practically retired. He leaves a son, Dr. P. M. Wood of Jamaica, and two daughters.

Dr. WILLIAM JOHNSON DALE died on October 7, at his home in North Adams, Mass., aged eighty-nine. He was graduated in arts from Harvard in 1837 and in medicine from the same university in 1840. He was appointed Surgeon-General of the State in 1860 by Governor Andrews. He served in the army throughout the Civil War as a surgeon. He was always greatly interested in sanitary matters and did much practical and efficient work in that science.

Dr. CORNELIUS SHEPERD died in Trenton, N. J., on October 7. He was born in Bucks County, Pa., in 1837, and was a graduate of the University of Pennsylvania in 1861. He was prominent in local politics and active in establishing the present school system of New Jersey.

Dr. JOHN B. JOHNSON of St. Louis died in that city on October 7, at the age of eighty-six years. He was born at Fairhaven, Mass., and was graduated from the Berkshire Medical College, Pittsfield, Mass., in the class of 1840. He was formerly professor of the principles of medicine at the St. Louis Medical College, and was one of the first vice-presidents of the American Medical Association. He had practised medicine in St. Louis over sixty years.

Dr. THOMAS J. L. KENNEDY, aged twenty-seven years, died at St. Vincent's Hospital, in this city, on October 8, of typhoid fever. Up to the time of his illness he had been President physician of the New York Foundling Hospital. He was graduated from the College of Physicians and Surgeons, New York, in 1900. He served two years as interne in St. Vincent's Hospital, three months in the Morgan Lying-in Hospital, and nine months as resident physician in the New York Foundling Hospital.

Dr. HAMILL M. ALEXANDER of Marietta, Pa., died on October 13 at the age of fifty-two years. He was a graduate of the Medical Department of the University of Pennsylvania in 1876. He was the owner of the Lancaster County Vaccine Farm.

(From Our Special Correspondent.)

NOTIFICATION—THE MIDWIVES' BOARD—STEPHEN COLERIDGE'S LOGIC—BEDLAM R.A.M. COLLEGE—DR. CANNEY'S SCHEME—SOCIAL SERVICE—TEMPERANCE HOSPITAL SURGERY—THE DUBLIN EPIDEMIC—MEMORIAL TO WM. CADGE—DR. PARKES—OBITUARY NOTES.

LONDON, September 25, 1903.

THE report of the Asylums Board for 1902, which has lately been issued, contains some facts about errors in reporting infectious diseases. This subject has been the source of numerous gibes in the press, and on that account deserves further notice in the light of official figures. Referring to the last epidemic of smallpox, it appears that mistakes of diagnosis were made in 600 cases, and these errors are attributed to the slight acquaintance of our practitioners with the disease. To afford them and students an opportunity of studying the disease the smallpox hospitals are in future to be utilized for clinical instruction. It is like some officials to make this concession after the epidemic. There are many doctors in full practice who have never seen a case of smallpox, and to whom, therefore, its features are only known by description. In the same way, though to a less extent, the isolation of other infectious diseases in the board's hospitals withdraws from the general practitioner's observation a considerable proportion of such cases. As notification is made compulsory, and as the authorities are ready to take proceedings for neglect of this duty, when the doctor delays to perform it, early notice is necessary to avoid vexatious prosecution. And yet it is in the early stage that difficulty is most felt. Indeed, experienced clinicians are so frequently uncertain at this stage that I cannot admit the infallibility of the medical officers charged with the reception of cases in the isolation hospitals. The report named above states that during the year 7,896 patients were landed at the Rotherithe wharves. Of these 7,842 were certified to be smallpox. Of these 607 proved not to be such. Over 200 were chickenpox, 74 were skin cases, 48 measles, 7 German measles, and 4 scarlet fever. There are two circumstances which must be taken into account in reference to errors in diagnosis. The proportion of mistakes was 7.7 as against 13.3 in the previous year, and the cases are now sent off at an earlier stage than formerly. Even the acting medical officer of the River Ambulance Service, Mr. W. M. Wanklyn, complains of this tendency to enforce early removal being carried to extremes, so that some patients reached him before any characteristic manifestation had appeared. But what is the unfortunate general practitioner to do? The least delay in notification is likely to bring him a summons—if he waits for a bacteriological diagnosis, the magistrate will hardly give him credit for good intentions, and when an epidemic is raging and neighbors falling victims, the alarm of the householder may take the initiative and thereby bring about a prosecution, if the case prove eventually one for notification. No wonder he feels inclined to notify and throw the responsibility on the hospital officers These points are aptly illustrated by the action of one of the Borough Councils asking explanations from their local practitioners of their differences of opinion with the Asylum Board's officers, and why in doubt they did not avail themselves of the "diagnosis test" which the council offered. No doubt the councillors mean well, and think they have grasped the matter, but they seem to have forgotten that they have no right to ask for any explanation or to exercise their judgment on the matter. When a doctor has notified a case he has no further responsibility. The local authority has only to pay the half-crown awarded by the act and carry out its own duties. There are councillors who think that half-crown ample remuneration. They should remember that in supporting notification the profession is sacrificing itself to the public. A case notified is a patient lost, and it would be difficult to estimate the monetary loss to the profession by this and other preventive measures which it has always supported.

The profession seems to be waking up from the apathy with which it permitted a few busybodies to pass the Midwives' Act. The regulations framed by the Midwives' Board and issued by the Privy Council come as a surprise on many who regarded with indifference the warning that an inferior class of practitioners was being created to feed the practice of consulting obstetricians at the expense of general practitioners. A midwife trained and examined and certified under Act of Parliament is not going to confine her work to attending the poorest women of her district under the direction of the doctor. She will sport her qualifications as freely as

the women who were certified by the Obstetrical Society which had no authority for its action, but which the apathy of the profession permitted without much remonstrance. It suited the consultants on the council, and ordinary members allowed them to act. A few warnings were raised, but disregarded until the Obstetrical Society's diploma became a scandal and its certificated midwives rival practitioners in the poorer localities, taking all the women and children and treating them on terms which medical men consider degrading. Fears are already expressed of an extension of the evil, but it is too late. The discontented ones should have taken warning before the act was passed.

The rules of the Midwives' Board tend to exalt rather than otherwise those trained according to them. They are being criticised as evidently largely due to those who do not understand the requirements of the poor, and who seem unacquainted with what has been done. For example, these rules seem to disqualify the women who have been trained at the Dublin Rotunda—one of the finest schools in the world, and give preference to the certificates of the Obstetrical Society, which really represent little more than a contribution to its funds.

When any disease is thought to be on the increase there are plenty of people who offer explanations of the supposed fact without waiting to inquire whether the observation is correct. Thus bicycling and other athletic exercises are alleged as causes of appendicitis, another self-sufficient know-all starts the rumor that frozen food is to blame. This last tale is considered worth serious refutation by Dr. Kent Hughes of Melbourne, who says appendicitis is much more frequently diagnosed in Melbourne, Sydney, and Adelaide than formerly, though frozen food is practically never eaten in Australia. A hundred years ago, or so, there was a talk of "suppressed itch" being on the increase. The discovery of the parasite of scabies put a stop to such stuff.

This week we have another example of this kind of thing. Mr. Stephen Coleridge writes to the papers with his usual disregard of logic to attribute an increase of diphtheria and typhoid fever to vivisection and the serum treatment. He quotes the Registrar-General's returns, and in doing so exhibits apparently an incapacity for statistical investigation. He would frighten the public by saying that antitoxin causes diphtheria and accounts for its increase—quoting rates per million of the population—instead of the case mortality. Further, he blames vivisectionists for the increase of cancer. Again some diseases for which there is no serum have decreased, because, he says, of the absence of that cause. He is, I believe, a graduate of Cambridge. Could you have supposed such logic could have proceeded from any one who had spent a term at the Mathematical University?

"Bedlam," as Bethlem Royal Hospital for Lunatics, to use its proper name, is still often called, is about to extend the accommodation for paying patients, a limited number being up to the present received at two guineas a week. The charity commissioners have just issued a supplemental scheme for dealing with the institution. One point of the scheme is that five houses in Lambeth Road belonging to the hospital may be adapted for a home for paying patients who are not certified lunatics but are suffering from neurasthenia and other ailments which, in default of treatment, may develop into insanity, the number not to exceed twenty, and the payment not to exceed four guineas per week. These figures, however, are not unalterable, as the scheme reserves power to the charity commissioners to vary them from time to time on the application of the governors. The hospital was founded in 1247 and incorporated by Henry VIII, 1547. It contains about three hundred beds. Of course this is a small number compared with the great county asylums of 2,000 and upward.

The War Office plumes itself on its action in creating the Royal Army Medical College. The result of the first course of instruction is satisfactory, so far as the examination for captains just held shows, as all passed. The reports from the staffs of the hospitals to which the officers were attached also testify favorably.

Dr. Canney's scheme for supplying armies in the field with boiled or sterilized water is beginning to attract the attention of the public, and much interest is expressed of the War Office. Some think such matters should not be discussed outside the services, but the *Times* lately devoted a leader to it, and public opinion is dissatisfied with the neglect of the official mind to examine all proposed plans of preventing disease in armies.

The Christian Union for Social Service, an unsectarian organization, maintains homes in Surrey and Westmoreland for poor epileptic children, and has now opened for epileptic boys whose friends can contribute something toward their cost. An inclusive sum for maintenance and education will be charged, varying in amount with the nature of the case. No doubt there will be no dearth of patients, indeed I learn that applications for such cases have often been received by the union, to which circumstance the new departure is principally due.

Sir Wm. Job Collins, among other officers, has long been surgeon to the Temperance Hospital. The Registrar, Mr. Hosford, has extracted from the hospital records the statistics of his operations. From 1888 to 1902 he performed 113 amputations with only two deaths. One of the fatal cases was morbus coxæ, amyloid degeneration, the other sarcoma of thigh, secondary growths in the pelvis and liver. This last case was the only one in which alcohol was administered.

The Hospital Saturday Fund is taking up the subject of sanatoria for workers suffering from tuberculosis, and has appointed a committee, of which Mr. W. G. Bunn is honorable secretary. It is hoped that by January next the various societies interested will have appointed representatives on this committee when the question of providing increased sanatorium accommodation will be discussed.

The epidemic of smallpox in Dublin seems to be over, according to a report of the Health Committee, after lasting up to July. The total number of cases was 255 with 33 deaths, a mortality of 12.9 per cent. The able M.O.H., Sir Charles Cameron, seems to have been alert at every point and his assistants never to have flagged in their efforts. The report is well worthy the attention of sanitarians.

The First Commissioner of His Majesty's Works and Public Buildings has appointed Dr. Louis Parkes consulting sanitary adviser to the department in succession to the late Professor Corfield.

A memorial to "Cadge of Norwich" is to be placed in the beautiful cathedral of that city, where he worked so long.

The deaths are reported of Dr. Wm. Bradshaw of Kensington on the 20th inst., in his eighty-fifth year. He took his M.R.C.S. in 1840 and his M.D. in 1854. John Ansell Brown on the 17th inst., aged seventy-six years, also of Kensington. He was formerly on the medical staff of the Indian Army and afterward superintendent of a suburban asylum. James Fergusson, F.R.C.S. Edin., of Richmond, on the 19th inst., aged sixty-seven years. Wm. Irving Page, M.R.C.S. (1862), on the 20th inst., surgeon to Wimbledon Cottage Hospital. J. E. Boyton of Watlington, where he practised upward of sixty years, on September 4, in his eighty-eighth year. He was connected with many local institutions. Walter Sumpter, M.D., of Cley-on-Sea, on the 9th inst., in his seventieth year. Staff-Surgeon W. J. Maillard, M.D. Lond., V.C., R.N., aged only forty years. William Turnbull, M.D., Demonstrator of Anatomy, Durham University, on the 20th inst., only forty-two years old, greatly esteemed by colleagues and students.

## OUR CANADIAN LETTER.

(From Our Special Correspondent.)

OPENING OF NEW MEDICAL BUILDING AT TORONTO—UNIVERSITY FOR THE AMALGAMATED SCHOOLS—DOMINION REGISTRATION RECEIVES A DISCOURAGING SETBACK—MUNICIPAL SANATORIA FOR TUBERCULOSIS—INVITATION TO THE BRITISH MEDICAL ASSOCIATION.

October 7, 1903.

A new era was signalized in the history of Toronto University, October 1, when the new medical department was formally opened. The leading universities of America were represented by members of their faculties and the large assemblage of graduates of the University made up a large gathering of medical men. The new medical building is constructed and equipped on the most modern and approved lines and marks the inauguration in Toronto of the best and most efficient accommodation for the teaching of scientific medicine. In all the addresses there were two dominant notes: first, congratulation that Trinity and Toronto Medical Schools had amalgamated; second, that Toronto University had at last a building splendidly equipped for the work of scientific research. The inaugural lecture by Professor Sherrington of Liverpool University was a comprehensive and scholarly review of the rise and progress of the science of medicine. The evening lecture was by Dr. William Osler of Baltimore, an alumnus of the University. His address was specially to the students assembled and, directing his remarks to them, he said, their master word, the great equalizer, the philosopher's stone, the magic wand that renders possible all things, is "work." To realize it, there were two things to bear in mind, not only knowledge of disease and of its cure, but knowledge of one's self. So far as professional education is concerned things are in a transition stage, and he regretted that the examination bugbear

was not left behind. He urged the students to realize that a degree was only the starting point of a long life. The first step is to have an interest in one's work. The next is the cultivation of systematic effort, and he specially asked those present for the first time to realize the profound importance of system and thoroughness in their work, to map out their day, so that due allowance might be given to each of their studies. Then artistic perfection of work was to be cultivated. It is this which makes anatomy the student's touchstone. While they should learn to love the freedom of student life, sequestration is essential to success. He referred to overwork and the danger of infection, but was strongly of the opinion that worry is the most general cause of nervous breakdown. The attitude of the practitioner should be to do the work of the day and take no heed for the morrow. In concluding, Professor Osler reminded young practitioners that they were entering upon a noble heritage and that they should endeavor to do what good they could for a suffering humanity. Much had been done; much remained to be done. The possibilities of medicine were limitless. Their duty was not to draw attention to their good works but to coöperate with the countless physicians and nurses whose voices were not heard but who brought consolation to the slums and the mining camps, to the homes of the rich and to the shacks of the poor; and to exercise sagacity, humanity and probity; in all circumstances true to themselves, true to their high calling and true to their fellowmen. Among others present, and taking part in the opening of the new building, were Dr. W. H. Welch, Professor of Pathology, Johns Hopkins; Dr. R. H. Chittenden, Yale; Dean Roddick, McGill; Dr. A. C. Abbott, Philadelphia; Dr. L. F. Barker, Professor of Anatomy, University of Chicago; Dr. Roswell Park, Buffalo; Dr. J. G. Adami, McGill; Dr. W. H. Keen, Philadelphia; Prof. Townsend Porter, Harvard, and Dr. J. P. McMurrick of the University of Michigan. The federation of the two great medical colleges of Ontario with Toronto University was thus given an auspicious inauguration.

The question of Dominion Registration, by which practitioners in one Province of Canada might be licensed to practise in the other provinces, is still a vexing problem. It seemed more likely to be achieved two years ago than it does to-day. Dr. Roddick, dean of McGill College, is also a member of Parliament for the city of Montreal, and his efforts have been untiring to secure what would certainly be most desirable legislation. His bill passed through the Dominion Parliament, and was to become law as soon as it received the sanction of the Provincial legislatures of the several provinces. These have all practically agreed upon the question with one exception—Quebec, for some reason, has defeated the measure. By the opposition of this one province Dominion Registration is for the present frustrated. The question forms a subject for lively discussion, and it remains to be seen whether the action taken by the one legislature shall keep the medical men of all the other provinces of Canada from enjoying what they have long and diligently sought for. The determined opposition comes altogether from the French colleges of Quebec, and present indications show that they have no intention of accepting the act as it stands at present unless amendments are made of a most damaging character. Thus the matter rests in a very unsatisfactory condition, and the prospects are clouded by the opposition coming from this one part of Canada. The only solution at present seems a new act by which all the other provinces would agree to Dominion Registration and leave Quebec out of the scheme altogether. Dr. E. P. Lachapelle, head of the Quebec Provincial Board of Health, and one of the chief supporters of the Roddick bill, expresses the conviction that his province will gradually be educated up to adoption of the act.

The establishment of municipal sanatoria for the treatment of tuberculosis is receiving some attention in Ontario. The open-air treatment has been attended with such pleasing results at Gravenhurst that there is now a growing sentiment in favor of having, convenient to each large municipality, an isolated pavilion supplied with all the requisites necessary to carry out that treatment. One especially notable fact is that the percentage death rate from phthisis in the Province of Ontario is certainly growing less each year, and this decrease is certainly due to the fact that the open-air treatment has been persevered in more faithfully in Ontario than elsewhere in Canada. Quebec has also a live league for the prevention of tuberculosis.

The British Medical Association is likely to come to Canada for its annual meeting in 1905. The profession in Toronto took the initiative, and the Canadian Medical Association has given the invitation such a hearty endorsement that there is every reason to anticipate a great medical assembly in the Queen City two years hence. The British Association was such a pleasing success when the meeting was held at Montreal in 1898 that many of the home members have expressed a desire to cross the Atlantic for another meeting.

## THE EARLY DIAGNOSIS AND TREATMENT OF TUBERCULOSIS.

To the Editor of the Medical Record:

Sir: I have been interested in your editorial notice, published in the Medical Record of September 12, of the article of Dr. Martell on the necessity of early diagnosis of tuberculosis, especially calling attention to some of the late refinements in diagnosis. Whether tuberculosis can ever be exterminated may still be a matter of doubt, but that its prevalence can be diminished to an unknown degree by modern methods is already well established, but physicians on the one hand and the public on the other are not doing all they can to further this cause. Notwithstanding all that has been accomplished by the pretty general recognition on the part of the medical profession that there is something to be done in a case of tuberculosis, and notwithstanding the great benefit resulting from the associations for the relief and control of tuberculosis which are springing up everywhere (the work of which is done largely by laymen) physicians and the people still fail to appreciate the importance of early diagnosis and prompt action. It is well to make known all new aids for making an early diagnosis, but what is especially needed is some means of urging physicians and people to a more general appreciation of the importance of applying at once means of diagnosis already well known.

It is my experience, and I think that of all consultants in such cases, that the infected patients have usually been allowed to go on for months before any attempt at careful diagnosis has been made, hoping against hope that the cough will disappear, or the fever prove malarial. This arises sometimes from a lack of appreciation of early diagnosis and sometimes from the same reluctance on the part of the physician to hunt for proof of such a dreaded condition in perhaps an intimate friend, as he would in his own person. This, however, causes loss of time, which may necessitate years instead of months of appropriate treatment. I have seen such a case within a week in which a gentleman (abundantly able to submit to proper treatment, if the importance of it had been impressed upon him in the beginning), had been allowed to remain at his business and treated for a cough for a whole year, never having been told that he had any pulmonary disease. He only applied to me after his strength was so exhausted that "he knew something must be the matter."

If the physician delays, it is not surprising that the patient should do the same, and in some way the public should be thoroughly aroused to the importance of early diagnosis, and at the same time informed of the possibility and even probability of cure if the disease is detected early.

While the medical press should continue to urge this matter on the profession, it seems to me that the lay press, which has always done such good service in the case of acute epidemics should be called upon to lend its forces to the effort to eradicate or at least diminish the prevalence of this very destructive disease. The press reaches thousands where bulletins issued by boards of health reach hundreds, and its services should be enlisted in urging upon all the importance of seeking medical advice at once in case of a continued cough. Patients may show no signs of being really sick until long after the infection with pulmonary tuberculosis, and yet the best time to eradicate the disease is before the system is much disturbed by it, a quick cure being often accomplished at this time. This cannot be too strongly urged on the profession by the medical journals and on the public by the lay press.

Frederick I. Knight, M.D.

Boston, Mass.

## CIRCUMCISION IN INFANCY.

To the Editor of the Medical Record:

Sir: The remarks on circumcision in infancy in the issue for September 26, by Dr. Wm. B. Harlow, surprised me not a little. The writer says "there is no possibility of any irritating collections occurring beneath the prepuce until maturity," etc. My experience is just the opposite. As I frequently find irritating smegma all around the corona before the infant is a month old. My candid opinion, however, is that very few children need be circumcized—that is, if they are cared for by the physician. His duty is to stretch its prepuce, and if the mucous membrane adheres to the glans all the way down to the meatus to take the flat end of a probe and strip the glans clean to the corona. He should then remove all smegma,

anoint the parts with vaselin and return the prepuce to the original position. Now the mother or nurse will have no difficulty in keeping the parts clean.

J. R. SHELLENBERGER, M.D.
5505 GERMANTOWN AVENUE, PHILADELPHIA.

---

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: An article published in the MEDICAL RECORD of September 26, entitled "Circumcision in infancy," by William B. Harlow, M.D., leads us to believe that the doctor's experience has not been in line with the majority of practitioners. One is almost tempted to believe that he is not thoroughly conversant with the current literature upon the affections of the infantile prepuce and glans penis. If the doctor means to refer only to normal cases there can scarcely be any contention as to his advice upon circumcision of the infant in order merely to get rid of the redundant tissue. All experienced practitioners have undoubtedly met with general or local conditions which proved to have had their origin in an adherent prepuce. Balanitis with adhesion of the foreskin is not a very uncommon occurrence in early infancy. Owing to defective drainage, the "pin-head opening" of the prepuce permits accumulation of the urine and irritation of the lining membrane. The straining thus occasioned has been known to produce balooning of the prepuce, hydrocele, varicocele, hernia, and prolapsus of the rectum. General or special reflex disturbances, such as convulsions, epilepsy, spasmodic contractions, choreic movements, paralysis, malnutrition, etc., are not uncommonly found. Such local conditions as dysuria, priapism, vesical irritation, general restlessness, especially at night, and preputial calculi are met with. The remark of the doctor concerning foreign substances in saying "there is no possibility of any irritating collections occurring beneath the prepuce until maturity, and not then until the semen has been called out and allowed to set back under the skin," savors of some of the so-called "osteopathic" literature.

In case of the pin-head opening, I do not hesitate to incise and trim the foreskin at an early day. Adhesion to the glans in such cases are almost constantly found, smegma and calculi may be present at a later period.

The following case is an example: Baby V. had manifested marked nervous symptoms from early infancy, among which was noted sudden starting from sleep, choreic movements, almost constant fretting, crying, etc. The family attendant was not a believer in circumcision. Operation was advised and done during the fifth month. The prepuce was so adherent to the glans that in order to effect its removal the mucous membrane had to be literally torn into shreds. Behind the corona was deposited smegma and calculi of the consistency of the tartar found on neglected teeth. The child immediately recovered from its previous symptoms. I might cite other cases of apparent epilepsy, convulsions, etc., which have promptly recovered after circumcision of an adherent prepuce. It is certainly an act of wisdom carefully to investigate the copulative organ in all cases of male infants who present symptoms of reflex or general disturbances and all local affections not assignable to other causes. If the organ is found to be the source of irritation a few strokes of the scissors and a half-dozen catgut ligatures will doubtless spare the attending physician the humiliation of learning at a later period that circumcision has been done to the entire delight of the family and especially the little one.

A. P. STONER, M.D.
DES MOINES, IOWA.

**Skin-grafting in Laryngeal Stenosis.**—Following a review of reported cases of this nature, A. H. Burgess mentions the case of a man of thirty-eight years who cut his throat. The usual measures were instituted, a tracheotomy tube being inserted through a separate opening below the self-inflicted wound in the trachea. Unfortunately, the wound became septic and broke down, finally healing by granulations. Later, evidences of laryngeal stenosis appeared, and examination revealed a fleshy mass below the cords, appearing to occupy the entire lumen of the tube. Laryngofissure showed that the lower part of the larynx and the upper part of the trachea was completely occluded by a dense cicatrix, one inch in vertical extent. This was removed and a gauze plug inserted. The latter was changed several times, and eleven days later was permanently replaced with a large Thiersch's graft from the thigh, rolled around a drainage tube of the caliber of the trachea. Good union ensued. The final result was perfect, and the patient was able to speak without difficulty.—*Medical Chronicle.*

# Progress of Medical Science.

*The Boston Medical and Surgical Journal, October* 8, 1903.

**The Operative Treatment of Umbilical Hernia.**—J. Collins Warren believes that the reason for the decrease in the percentage of recurrences after operation for umbilical hernia is due to the attention paid to an accurate suture of the different layers in a manner that will bring them into close contact without too much tension. The hernial sac should be exposed by two slightly curved incisions on the median line, which should meet and blend above and below into an incision long enough to expose the outer walls of the sac as far as the neck of the sac and the surrounding aponeurosis. The sac should then be opened and the contents freed from adhesions and returned into the abdominal cavity. If the omentum is much matted it should be excised below that part which usually occupies the sac. The sac is then carefully excised. The abdominal opening is an oval with the long diameter lying at right angles to the linea alba. The peritoneum should, if possible, be separated from the fascia and sutured with fine sutures. The accurate coaptation of the edges of the hernial ring is of the greatest importance. Great tension is caused by bringing the right and left edges together. So if the lower and upper margins of the ring are brought together by forceps they can easily be held in that position without exercise of any appreciable degree of force. If the opening is closed transversely, the parts seem to fall naturally together. Lateral strain closes this opening in the linea alba, while vertical strain tends to open it. A new feature in the treatment is the removal of the thick layer of adipose tissue. In eleven cases operated on by the writer by this method, there has been only one recurrence during periods varying from one to thirteen years.

*Journal of the American Medical Association, Oct.* 10, 1903

**Scarlet Fever.**—W. L. Baum analyzes 628 cases seen in one of the Chicago hospitals during a period of seven years. He reviews the work of recent investigators as to a bacterial cause of the disease and does not find any direct support of the theory of streptococcus etiology. He calls attention to the difficulties of differential diagnosis, stating that certain cases sent to the hospital as scarlet fever turned out variously to be erysipelas, cerebrospinal meningitis, measles, tonsillitis with erythema, influenza and (one case) septic typhoid. Mixed infection was present in 142 cases, with 17 deaths. Diphtheria was the most common, 96 cases. The author's experience has convinced him that the disease is infectious during the incubation period. He also notes that in differential diagnosis we must take account of drug eruptions (quinine, chloral, opium, coal-tar derivatives must be taken into consideration, for not only are the conditions for which they are prescribed accompanied by fever, but the drug eruptions frequently start on the face and locations characteristic also of the scarlet fever eruption. Also, toxic erythemata occur in the course of septic infections, which are frequently mistaken for scarlet fever eruptions

**A Deviation from the Usual Methods of Closing Abdominal Wounds, Including Hernia.**—O. O. Witherbee has adopted silkworm gut for all suturing. He thus describes his method of abdominal closure. The peritoneum is first approximated and the ends of the suture are brought through the integument near the extremities of the incision. This permits of ready removal any time from the third to the sixth day. The abdominal fascia is then brought into apposition by the ordinary figure-of-eight sutures, except that the ends, instead of being brought out near the margins of the wound, are carried by long curved Hagedorn needles through the adipose tissue to emerge on a line parallel with the abdominal incision and from one and one-half to two inches on either side of it. These ends are passed through notches in the lateral bars of a U-shaped or rectangular framework, made from aluminum or hard rubber, the outer dimensions of which measure from three to four inches in width, and from four to six inches in length. The sutures are then tied in pairs on each side, respectively, with just sufficient tension to approximate the fascia. On one side the ends should be tied in a bow-knot, allowing of alterations in tension if necessary. The skin incision is next closed by a subcuticular suture, and when completed strips of sterile gauze are drawn beneath the plate and a moist bichloride dressing placed over all. The same tactics are made use of in the treatment of hernia, except that the peritoneal suture is quilted back and forth through the neck of the sac, and its ends carried well above the internal ring, where they are brought through the tissues and secured to the upper part of the framework, said suture to be removed at the end of one week. In approximating the conjoined tendon with Poupart's ligament, the tension should be exerted on a plane to correspond with the re-

sistance to be overcome. The author illustrates his idea with several excellent diagrams, and claims that his method approximates all the layers snugly, yet is free from the tension on the skin which is so annoying and even painful to patients.

*New York Medical Journal, October* 10, 1903.

**Still Birth Due to Strangulation of the Funis.**—J. Milton Mabbott reports the case of a full-term child. As the body was born the cause of still birth was seen to be a condition of strangulation of the cord, which took a spiral turn around the right upper arm, emerging from the front of the axilla, thence passing around the back of the neck on its way to the umbilicus. The cord was about seventeen inches in length, and the point of strangulation was at the axilla, where it was gripped very tightly by the arm.

**The Dangerous [Operation of [Uterine Curettage.**—E. Van de Warker calls attention to the many risks attending this operation and narrates several case histories which show its sad results when unskilfully done. Preliminary cleansing of the vagina should be done with the patient in the semi-prone position. In this position with the hips slightly elevated the cervix may be submerged in the antiseptic solution and the dilatation and other steps carried on through it. Biniodide solution is better than bichloride. The vulsellum forceps should be carefully inserted so that it will not tear out during dilatation and thus leave a track for infection. This instrument should not be removed until the operation is over. Dilators with ridges on the outer sides of the blades to prevent slipping are dangerous instruments. The blades should be opened slowly. Graduated sounds are safer than any spreading-blade instrument. Only that degree of dilatation should be made which is sufficient to allow the free use of the curette with gauze strips for drainage. Certain uterine conditions forbid forcible dilatation, *e. g.* postpartum fatty degeneration for eight to ten weeks, abortion for six weeks, malignant disease, senile endometritis, etc. Curettage ought not to be followed by solid packing of the cavity. Only a strip should be used, and this should be removed if, after a few hours, drainage stops. The strip, which the fingers of the operator should not touch, should be introduced, while the perineum, the labia, and the thighs of the patient are covered by clean sterilized napkins, applied at the last moment before the gauze is introduced.

**Transient Post-convulsive Astereognosis in Jacksonian Epilepsy.**—This symptom, signifying inability to recognize objects by contact, was in a patient of C. W. Burr, associated with and due to the inability to distinguish the number of points of contact though tactile sensibility itself was preserved. His patient was a woman of fifty-eight, with a history of eight years' duration. Sensibility to touch, temperature and pain was normal at all times, but when astereognosis was present she was unable to distinguish between one and several points of contact on the right hand unless they were very far apart. This was the only sensory disturbance she ever showed. She knew the position of the hand with the eyes shut. While in the hospital she had several convulsions like the following: she suddenly began to cry, complaining of pain in the right arm and leg and begging to have them rubbed. In a few moments the right arm and leg became rigid in tonic spasm, followed almost immediately by violent clonic spasm of the entire side, including the face. Soon the face became blue and the breathing stertorous. Finally, slight tonic spasm appeared on the left side and she lost consciousness. The attack lasted about five minutes. After it she was dull and stupid for about an hour, and there was a complete flaccid palsy of the right side which passed off in the course of several hours. Several times, but not always, when consciousness had fully returned and the temporary increase of the palsy had passed away, she was for several hours unable to recognize by contact objects placed in her right hand, though sensibility was preserved to all forms of stimuli, except that, as stated above, she could not tell whether she was touched by one or both points of the æsthesiometer. Objects put in the left hand were readily recognized and named. The diagnosis in the case was cerebral thrombosis with softening in the area of distribution of some branches of the middle cerebral artery.

*American Medicine, October* 10, 1903.

**Insanity as a Sequel to Physical Conditions.**—A. B. Richardson states that all persons mentally defective from imperfect development or congenital physical deficiency are more susceptible to acute attacks of active insanity in later years. A second class of more than usually susceptible individuals, so far as liability to subsequent insanity is concerned, are those who are structurally out of balance: those in whom there is not a proper relative development of the different parts, even though their organization may not disclose any actual deficiency in any part. Cases in the former class are quite numerous. They develop slowly and insidiously. They may show an unusual lack of self-control in some direction. The resulting insanity is usually an exaggeration of these preëxisting peculiarities. In the second class of cases the insanity is due chiefly to acute exciting causes. This cause may be traumatism, or acute disease, or intoxication. In studying a case of mental disease the following points should be considered: (1) How much influence had original and natural defect or nervous instability in the development of the conditions found? (2) Do the assigned exciting causes bear a reasonable relation to the form of mental disease existing? (3) Can you exclude all other causes that might more probably produce the same condition? The capacity to make a safe deduction from a given group of facts comes only from a long and varied experience and careful study of the insane.

**Pyloric Carcinoma with Symptoms Resembling Those of Gastrocolic Fistula.**—David L. Edsall and Charles A. Fife report the case of a man aged fifty-nine years. His former history was good, although in April and May, 1900, he had a severe gastric attack. It was thought for a time that he would die, but he recovered and seemed entirely well for two years thereafter. He then began to exhibit signs of dyspepsia and soon vomiting appeared. He was believed to have cancer and also gastrocolic fistula, because of the persistently feculent vomiting, the rapid onset of this vomiting with the ejection of shreds of tissue, the result of inflation of the bowel, and the result of the examination of the vomited material after the treatment with enemas had been instituted. It seemed impossible that the vomit could contain so much fat as it did when nothing was being taken by the mouth, unless the enemas were being vomited; and it seemed almost certain that these enemas were being passed from the bowel into the stomach through a fistula. The vomit was a rather thick, brownish fluid, filled with small granular particles and having a most offensive feculent odor. There was a multitude of bacteria, and great numbers of fat-droplets. Prostration increased and the man died. At autopsy there was found an annular cancer of the pylorus. There was not the slightest sign of any communication between the stomach and the bowel. The pylorus was perfectly rigid and incapable of contraction. There was no peritonitis and no sign of obstruction of the bowel. The accurate recognition of the conditions actually present in this case would seem to have been practically an impossibility. The case was undoubtedly an instance of feculent vomiting in gastric cancer, without any communication between the stomach and the intestine, or any obstruction of the intestine. This condition seems to be extremely uncommon.

*The Lancet, October* 3, 1902.

**The Immunization of Animals to the Bacillus Typhosus.**—W. V. Shaw details his experiments, from which he draws the following conclusions: (1) The best method of obtaining a typhoid toxin is by the digestion of the bacilli. (2) This product is toxic. (3) This product can excite a reaction in susceptible animals during which they develop immunity to the injection of living typhoid bacilli and the serum from such an animal can protect another animal against typhoid infection. (4) The injection, intravenously, of living typhoid bacilli may result in the production of a "negative phase" of resistance.

**A Case of Faciohypoglossal Anastomosis (Körte-Ballance Operation).**—The patient, a woman, was operated on by J. H. Nicoll. The facial and hypoglossal nerves were located respectively above and below the posterior belly of the digastric. That muscle having been excised the facial nerve was divided close to the stylomastoid foramen and the hypoglossal near the occipital artery and united end to end. The wound healed by first intention and the patient is now under electric treatment for the facial muscles. At present both the right side of the face and the right side of the tongue are paralyzed. The condition of the tongue appears to cause the patient little inconvenience in feeding or speaking. The operation is still a comparatively new one. The author asks—Will movement return to the facial muscles when it is done for peripheral facial paralysis, and if so, will such movement be "associated" (tongue-face), or will "education of the cortex" secure disassociated movement? In regard to the tongue, he asks what will be the condition (in case of development of disassociated movement) of the paralyzed half of the tongue? He suggests the possibility of grafting the end of the severed distal portion of the hypoglossal on the distal portion of the opposite and intact hypoglossal. There may be a temporary paresis of the healthy side, but the author thinks that careful operating will reduce this to a minimum In the event of its occurrence its effects might be obviated by temporary fixation of the tongue to the floor of the mouth by anchoring sutures, and feeding by tube—nasal or oral.

**The Circulation of Tissue Fluid in Man.**—From the observations of Geo. Oliver, the following facts are brought out: (1) The amount of tissue lymph varies during the day and each variation is of short duration. (2) The injection of food causes a rapid flow into the lymph spaces. (3) The digestive curve of variation follows a uniform rule of rapid rise, short acme and gradual subsidence. (4) As the digestive lymph wave develops, there is a rise in the percentage of cells, hæmoglobin and specific gravity of the blood. (5) As the digestive wave declines, there is a corresponding decline in all three. The general office of the intermediary lymph circulation is a three-fold one: (1) It provides the mechanism, as it were, for the supply of pabulum to the tissues and for the removal of soluble waste products from them. (2) The lymph wave which follows a meal insures the immediate supply of pabulum from the blood which restores all the tissues of the body at once and long before the food itself can be assimilated into the blood. Thus it is that the ingestion of food secures the speedy renewal of the energies, which is a matter of common experience; and therefore the exhausted tissues have not to remain unsupplied with fresh nourishment until the food taken becomes part of the common store of pabulum which the blood keeps ready for distribution. (3) Beverages (tea, coffee, alcohol) probably invigorate the body by inciting a flow of lymph into the tissues. Beverages, however, viewed from this standpoint, differ from foodstuffs in that they fail to restore to the blood the outflow of pabulum they create. They are therefore but temporary expedients of nutrition. The author believes that these views may have a bearing in gout, for he is convinced that it depends on a derangement of the intermediary circulation, and that therefore the tissues themselves form the arena in which gouty disturbances develop and manifest themselves. Residua may accumulate and be deposited in the interstitial spaces of the tissues, because their removal is thwarted, either by an excessive capillary blood-pressure limiting the absorption of fluid from these spaces or by a diminution of that pressure reducing the fluid exchange between the blood and the tissues. Hence the two leading types of gout which are well recognized. According to the author's observation, the continuous presence of a large quantity of tissue lymph provides an important condition for the development of the local manifestations of gout, which were present in by far the majority of the cases observed, and those few cases in which local signs of gout had not so far declared themselves might fairly be said to be gouty—in the sense of potential gout.

*British Medical Journal, October* 3, 1903.

**Poisonous Effects of Ricinus Communis.**—W. J. Burroughs reports a case of poisoning from castor-oil seeds. The patient was a man of fifty years. Soon after eating two of these seeds he was seized with symptoms of poisoning. The contents of his stomach were evacuated and he was greatly relieved. The next day he felt comparatively well. The seeds were proved to be castor-oil beans. They were rather dried-up specimens.

**On the Nature of Fragilitas Ossium in the Insane.**—W. Maule Smith presents a valuable paper on this subject. He gives the results of an analysis of 200 cases from the post-mortem records of the Wakefield Asylum. There were 27 cases of idiocy or imbecility between the ages of 6 and 78. Excepting one case, no fragility occurred until after the 40th year. The exception was a male of 26 years, in whom the condition was slightly present. Of 11 patients dying after 40, fragility was present in 8 and absent in 3. Of the 8 cases 4 were males and 4 were females; of the 3, one was a male and 2 were females. Eighteen patients died of chronic mania. No fragility occurred up to the age of 44. After this age it was absent in only 2 males. Seventeen patients died suffering from chronic melancholia. Brittleness was absent in only 2. It was always slight in the males but marked in the females. In the cases of general paralysis, only 3 males out of 25 cases showed pronounced fragility. In 11 out of 14 females this change was very pronounced. The percentage of cases of dementia is the highest, those of epilepsy the lowest. The disease is more frequent in the female sex and occurs at an earlier age than in the male. It is comparatively rare before the ages of 45 or 50, except in general paralysis. It is essentially a morbid change, which occurs in late middle life and old age.

**Preliminary Note on the Action of the Blood Serum from Subjects of Mental Disease on B. Coli Communis.**—A. V. Johnson and E. Goodall present the following summary: Good agglutination shown in four out of five cases of acute melancholia, one out of three cases of general paralysis of the insane, one out of two cases of delusional insanity, and in one case of climacteric insanity. Partial agglutination shown in six out of eleven cases of acute mania, one out of two cases of delusional insanity, and one case of alcoholic insanity. No agglutination in five cases of mania, one of melancholia, one of puerperal insanity, two of general paralysis, and one case of recurrent mania. The agglutination is present in 60 per cent. of all cases, 28 per cent. good agglutination, 32 per cent. partial agglutination; only one control showed a slight partial agglutination. The greatest number of both good and partial agglutinations were obtained from a virulent culture of B. coli communis with a dilution of 1 in 100. Another interesting point that is being investigated is the leucocyte count in various forms of insanity. The white cells are found to be in much greater numbers when the patients are passing through acute states, running then as high as from 30,000 to 40,000 per one c. mm. of blood, and falling again to 15,000 and 10,000 during stages of remission and in cases of recovery.

*Deutsche medicinische Wochenschrift, September* 17, 1903.

**Spread of Diphtheria.**—K. E. Büsing shows how nurses may disseminate diphtheria. A nurse employed in a child's hospital into which contagious diseases were never received, complained of sore throat on March 11, but remained upon duty until March 24, when a culture was taken from her throat, the bacteriological examination of which showed the presence of diphtheria bacilli. Three of the children whom she was attending sickened of diphtheria on March 16, 22, and 27, respectively. All other sources of contamination were excluded.

**Physiological Action and Pharmacodynamics of Silicic Acid.**—H. Schulz thinks that silicic acid is an important ingredient of certain of the body tissues, and that as a therapeutic agent it possesses a greater degree of activity than has been hitherto supposed. By analysis it may be found in many of the body tissues, and is especially abundant in those which are particularly rich in connective tissue, such as the tendons and fascia. Indeed extended observations show that it is an important and essential constituent of connective tissue, holding thereto a similar relation as phosphorus to nerve tissue. It is interesting to note that in the lower animals and in young human beings silicic acid is very much more abundant than in human adults. The reason for this is not entirely clear. It is known, however, that in certain organic combinations the silicon may be replaced by carbon, giving rise to carbon compounds. It may be supposed that the silicon compounds are especially abundant in the lower animals and young adults, but that in human beings, as age advances, the silicon is replaced by carbon and the quantity of silicic acid in the tissues correspondingly decreases. The feeding of silicic acid in large quantities to healthy men shows that it is by no means a negative substance. It produces no symptoms in the respiratory, circulatory, or lymphatic systems, but it gives rise to irritability of the nervous system, digestive disturbances, cutaneous eruptions, and a peculiar feeling of weight and stiffness in the extremities. Also at times the joints become painful and swollen.

*Berliner klinische Wochenschrift, September* 21, 1903.

**Vegetable Nutrition and Drinks in Gout and Nephritis.**—J. Walker Hall shows that many vegetables and grains, such as potatoes, beans, oats, and asparagus, contain a considerable amount of the purin bases. Also that the same are abundant in various brands of beer and porter. These substances should, therefore, be limited or excluded from the diet in gout and nephritis.

**Hysterical Autosuggestion of Children.**—C. A. Ewald describes three cases of a hysterical nature in which the nervous symptoms were produced by local irritation. In the first case the child had swallowed a bone and complained that it had lodged in the intestine. The boy pointed out the tender spot, which was in the left iliac region, and upon pressure over the region there was elicited marked pain and tenderness. No resistance or tumor, however, could be detected. Upon suitable hysterical treatment all the symptoms vanished. The second case might be designated as "hysterical appendicitis." This likewise succumbed to similar treatment. The third case was characterized by violent hysterical attacks, the cause being cerebral irritation due to overstudy.

**Action of Bile upon the Heart and the Cause of the Retarded Pulse Rate in Jaundice.**—Kurt Brandenburg by a series of experiments upon animals shows that a small amount of bile introduced into the circulation irritates the nerves of sensation of the heart, and in this manner by reflex action through the vagus produces a retardation of the heart's action. If large quantities of bile are introduced it acts directly upon the cardiac muscle showing the heart's beat and if the quantity of bile be large enough, completely paralyzing its action. The biliary acids are the constituents of the bile which produce this effect. In jaundice it is probable that both of the above

named factors are responsible for the retardation of the heart's action. The reflex action is at first operative, but with the continued accumulation of bile in the blood a direct effect upon the cardiac muscle sooner or later becomes operative.

*Münchener medicinische Wochenschrift, September 22, 1903.*

**Treatment of Abortion.**—Max Nassauer strongly advises the initial use of the tampon, and says that a mechanical evacuation of the uterus should only be attempted when a properly applied tampon has either failed to control the hemorrhage or incite the uterus to expel its contents. For use in such cases he has devised an abortion forceps which is a modification of Winter's instrument in that the shank is bent to correspond with the uterine curve and a device is placed at the end of the handles so that the blades are not easily closed. This prevents the apex formation at the extremity of the blades when they are closed, as in Winter's pattern, and removes all danger of penetrating the uterus, which has not infrequently occurred with the use of sharp-pointed forceps. When desired the blades may be fully closed and tissue which is to be removed tightly grasped.

**Movements of the Stomach and Intestines under Various Influences as Depicted by the Röntgen Rays.**—Felix Lommel has used the Röntgen picture in order to ascertain the effect of various influences upon the movements of the stomach and intestines. A good picture may be obtained by the administration of a fair amount of chopped beef, to which about 15 per cent. bismuth subnitrate has been added and immediately submitting the patient to the rays. In this way the movements of the stomach during digestion may be plainly observed. If warm applications are applied to the epigastrium no change from the normal is observed, except that the size of the waves at the beginning of stomach digestion is slightly decreased. The duration of the stomach digestion is in no wise altered. No effect was noticed as the result of cold epigastric applications. Psychical influences usually have a marked action in lessening the force and rapidity of the gastric waves during digestion, although the reverse is sometimes true—the results under these conditions being probably due to the character of the psychical influence present.

**Prophylaxis of Postoperative Cystitis.**—K. Baisch says that the cystitis which so frequently follows gynecological operations is, in the majority of cases, due to an infection of the bladder by the catheterization employed for the relief of the urinary retention so common after these operations. For this reason the use of the catheter should be avoided whenever possible. A very successful method of producing an evacuation of the bladder is by the means of boroglycerin (2 g. boracic acid in 100 c.c. glycerin) injections. If upon the evening of the operation the patient passes no urine a Nélaton catheter is introduced, and as soon as the first drops of urine begin to flow 20 c.c. of the above boroglycerin solution is slowly injected by means of a syringe through the catheter into the full bladder. This is usually followed by a complete evacuation of the bladder. This process should be repeated as often as necessary, but in most cases after a short time the urinary functions is completely restored. When this method is unsuccessful—that is when the desired result is not obtained within one hour after the injection—catheterization becomes imperative. This should be carried out with all possible antiseptic precautions, and immediately after the bladder has been emptied of urine it should be washed out with 500 c.c. of a 3 per cent. aqueous solution of boracic acid.

### *French and Italian Journals.*

**Physostigmine in Atony of the Intestines.**—According to Guglielmo Curlo, this drug acts as an excitant to the muscle walls of the intestines, causing spasm and increased peristalsis. It is indicated in atony, contraindicated in spastic constipation, in acute and chronic intestinal catarrhs, and in mucomembranous enterocolitis. It is of value in meteorism. The normal daily dose is two-thirds of a milligram. Symptoms of intolerance are myosis and diarrhœa. The best way to administer the drug is pills composed of the salicylate of physostigmine.—*La Riforma Medica*, September 16, 1903.

**Infective Splenic Pseudoleukæmia in Children.**—Francesco Scalese holds: (1) that among the most obscure causes of this affection, in addition to rachitis and syphilis, is diabetes in the parents, especially the mother. (2) Out of 15 cases in the author's practice, there was maternal diabetes in 10, maternal and paternal in 1, and hereditary syphilis in 3. (3) From cases observed by the author it is evident that the milk of mothers suffering from diabetes is able to convey the infection. Nursing therefore should be forbidden in any case in which diabetes is suspected.—*Giornale Internazionale delle Scienze Mediche*, September 15, 1903.

**Hysteria Occurring Before the Age of Two Years.**—Le Ridant states that from a number of cases observed, he has reached the conclusion that hysteria may occur in children under two years of age. This may be confirmed by a study of the previous history of children over two years of age who are clearly hysterical, giving such phenomena as paralyses, rages, swooning, croupy cough, certain forms of tetanus, etc., belonging to the same neurosis. We may also follow the subsequent history of young children whose symptoms have puzzled us, and discover their nature in this manner.—*Journal des Praticiens*, September 19, 1903.

**Local Anæsthesia in Dental Operations.**—Julien Tellier recommends Schleich's method of injecting cocaine, which avoids all pain preceding the anæsthesia. The solution used contains of the hydrochlorate of cocaine 0.20 grams, hydrochlorate of morphine 0.02, chloride of sodium 0.20, 5 per cent. solution of carbolic acid, 3 drops distilled water 100 gr. Schleich holds that the solution produces anæsthesia first by the ischæmia caused in the regions in which it is infiltrated; second by compression of the nerve filaments against the connective tissue walls by the fluid, which interferes with their conductibility; third, chilling of the region from the ischæmia, and fourth, action of the medicaments on the nerve-endings. This solution produces quite as complete anæsthesia as cocaine alone.—*Lyon Médical*, September 6, 1903.

**Dysentery, a Septicæmia.**—M. Guibaud holds that this disease has been proved to be due to a specific microorganism, the bacillus of Lesage. Blood poisoning it is which gives rise to the general symptoms, to the alteration of the blood cells, the consecutive anæmia, scanty urine, slow pulse, chilling of the extremities, and in severe cases hyposthenia. Treatment consists of a rigid milk diet and injections of the antitoxic serum of Lesage. When an increase in the amount of urine shows that the toxin in the system is being neutralized and the blood disappears from the stools, a local treatment only may be needed to combat secondary infection in the intestines. This should consist of rectal injections of a 1 to 1,000 solution of silver nitrate persevered in until the stools tend to become normal. The milk diet should be absolute during this period and a light diet of purées, eggs, cream begun only when the stools are formed.—*La Presse Médicale*, September 19, 1903.

**The Action of Ferruginous Mineral Waters in Anæmia and Chlorosis.**—R. Wybauw concludes that bicarbonate iron waters (Spa and Schwalbach) have a decided therapeutic action in doses containing an amount of iron which would certainly be inefficaceous if given in a pharmaceutical preparation. This is probably because the metal is in solution in its most unstable salt. Surroundings, air, climate, all play an important accessory part in the treatment, but could not of themselves produce the clinical results obtained. The benefit of the treatment continues after the latter is ended. Should the stay at the springs have been too short to bring about complete restoration to health, preparations of iron may be administered and will be of value, although previous to the treatment they may have been useless. These acidulated mineral waters do not cause constipation, but on the contrary, frequently cure constipation due to anæmia. External hydrotherapy have a favorable action, but are of little value unless combined with the internal administration of the waters. —*La Revue Médicale du Canada*, September 23, 1903.

**Serum Therapy in the Typhoid Fever of Childhood.**—Albert Josias states that from observations made in the Paris hospitals for children, it has been found that from March 1, 1902, to March 1, 1903, the mortality when cold hydrotherapy was used was 14.2 per cent. In the author's service, at the Bretonnean Hospital, during the same period, when serum therapy was combined with hydrotherapy, the mortality was 4 per cent. The author does not wish to be over-enthusiastic in regard to this treatment, nor to consider its value absolutely proved until more cases shall have been reported, but he says that his experience is borne out by that of Chantemesse, who asserts that the injection of antityphoid serum added to balneotherapy greatly diminishes the mortality in typhoid fever. —*Gazzetta Medica Lombarda*, September 6, 1903.

**Adrenalin in Ophthalmological Therapeusis.**—A. Ivert says that in acute catarrhal conjunctivitis a drop of the solution of adrenalin, 1 to 1,000, instilled two or three times a day, causes a more rapid cure than any other medicament. It is, however, more efficacious in certain forms of conjunctivitis than in others, as in rheumatismal conjunctivitis, ocular congestion of an arthritic nature, hay-fever, and, above all, in sclerotitis and episclerotitis. In the latter affections it is almost marvellous, bringing about a complete cure in from four days to a week. In cases of iritis, adrenalin with atropine and cocaine is of the utmost value; in glaucoma it is helpful in cases in which

operation is impossible, for one reason or another. It gives good results in chronic iridochoroiditis, and in retinal hemorrhages. It has an anæsthetic action in cases of cauterization, and its application greatly assists in many surgical operations on the eye.—*Recueil d'Ophthalmologie*, August, 1903.

**Narcosis by Means of the Chloride of Ethyl.**—Filippo Carta has used this substance for narcosis in cases of minor surgical operations in pleurotomy with resection of the ribs in the enucleation of glands, the reduction of luxation of the elbow, paracentesis of the membrana tympani, etc. He considers it an excellent anæsthetic in all interventions of short duration. It is well supported in cases in which chloroform and ether would be dangerous (circulatory disorders, fatty degeneration of the heart, diseases of the respiratory tract, cachexia, hemorrhages, grave traumatism). Complete unconsciousness occurs in from a minute and a half to two minutes. A return to normal occurs a few seconds after the mask is removed. In major operations it is not prudent to use this remedy, as it has not as yet been determined what possible lesions may be produced on the visceral organs by large amounts of chloride. In mixed anæsthesia the chloride of ethyl eliminates the long and dangerous period preceding anæsthesia.—*Giornale Medico del Regio Esercito*, August 31, 1903

**Death and Accidents Due to the Dependent Position in Abdominal Surgery.**—F. Jayle holds that the Trendelenburg position is responsible for many casualities. When there is any cardiac lesion, the extra strain put upon the heart may bring about a fatal result, or leave a weakness which will later cause death. In such patients, as well as in those suffering from obesity, atheroma or ascitis, the right side of the heart is the one chiefly affected; this occasions congestion of the lungs, sometimes resulting fatally. Moreover, as the dependent position causes depletion of the pelvic veins, hæmostasis may appear to be complete, and oozing follow a return to a normal position. Another occurrence of less grave import, is the possible entrance and retention of air in the abdominal cavity. The intestines fall back against the diaphragm, leaving the pelvic cavity free, and unless the patient is lifted back into an upright posture during the operation, and the iliac fossæ pressed upon to expel the air, some of it will be imprisoned and cause painful subcutaneous emphysema. Partial paralysis of the lower limbs may occur from the Trendelenburg position, but can be avoided by the application of suspension bandages to the shoulders and other parts of the body.—*La Presse Médicale*, September 16, 1903.

**Traumatic Rupture of the Small Intestines.**—Charles Juilliard believes in exploratory laparotomy in doubtful cases. He also gives points for the diagnosis between contusion and rupture of the intestines. To avoid peritonitis there are two measures: The first, whose value will be clearly demonstrated in the future, consists in strengthening the resistance of the organism against infection by increasing phagocytosis, and this by means of the injection of special serums. The second consists in clearing the peritoneum of septic matter. To accomplish this, physiological serum, at a temperature of about 98.6° F. should be poured into the abdominal cavity in large amounts until from thirty to sixty quarts have been in contact with the peritoneum. Without being actually brusque, a certain force must be given to the fluid, as the mechanical action is the chief advantage of the procedure. The fluid should be made to spread by slightly shaking the loops of intestine. When the fluid returns perfectly clear and the peritoneum appears to be clean, the washing may be stopped. This treatment is well borne by the patient, and the tendency to shock is overcome. The pulse increases in frequency and in fulness. Parts inaccessible to tampons can be reached by these washings. They are contraindicated in cases of localized infection in which the rupture of adhesions and diffusion of septic matters in a non-septic peritoneum is to be feared.—*Revue Médicale de la Suisse Romande*, September 20, 1903.

**Intestinal Lithiasis.**—N. Van De Velde-Coosemans discusses this disease, citing a number of cases. In the matter of treatment, the first symptom to combat is pain. This may be overcome by hot abdominal compresses, or laudanum poultices. Morphine may have to be given hypodermically. At the same time the intestines should be washed out with glycerinated water. Should the latter cause the evacuation of copious stools with much sand, the crisis will be terminated, but an irritable and painful condition of the intestines will remain, which should be treated by oily lavements at first, later by copious washings with water containing some medicament, such as the biborate of sodium, which is antiseptic and non-irritating. The use of intestinal washings should not be abused: the physician himself should administer them according to indications, and he should exercise extreme care as to the temperature, the amount of water and the pressure. Belladonna should be pushed to pupillary dilatation and dryness of the throat. The crisis over, treatment should be directed to the prevention of its recurrence, and this is effected by treating the mucomembranous colitis. Tact and patience will be required, for the affection is extremely stubborn. It is always preceded or accompanied by a special condition of the gastric secretions. Diet and hygiene are of the utmost importance in the treatment.—*Société Médico-Chirurgicale d' Anvers*, July-August, 1903.

**Intestinal Cancer in Youth.**—E. Saint-Jacques and L. Parizeau report the case of a boy of eleven years who was brought to the hospital because of incoercible vomiting and distended abdomen. Pulse was 110, temperature normal. Other treatment proving of no use, laparotomy was resorted to and an epithelial cancer removed from the sigmoid flexure. The child died of shock. From a study of this and other cases the author concludes that intestinal cancer often develops insidiously, giving no other symptom than chronic dyspepsia, and causes a sudden crisis of intestinal occlusion without premonitory warning. It is met with in youth more often than in adult life. Laparotomy should be resorted to if medical treatment be of no avail.—*L'Union Médicale du Canada*, September, 1903.

**Rapid Atrophy of the Large Cirrhotic Liver in Infections.**—M. Marcou treats of the care of persons who eat heartily, drink constantly (without being absolutely alcoholics), and exercise little; who are apparently in perfect health and yet have hypertrophied livers. Cirrhosis follows in the course of time. The author calls these cases of toxialimentary hypertrophic cirrhosis. In overnourished, rich patients, the hypertrophy represents a compensatory activity of the cells, and may be prolonged indefinitely if the patient can be brought to realize the necessity of care. In the poor man who is insufficiently nourished and drinks poor alcohol, cirrhosis occurs at once. Yet, even in the former case, should a grave infection occur, the liver is unequal to the strain, atrophy may occur with rapidity, or the patient may recover and the liver undergo a slow process of sclerosis. In any case a fatal end is inevitable.—*Archives Générales de Médecine*, September 8, 1903.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A SURGICAL HANDBOOK. By FRANCIS M. CAIRD, M.B., and CHAS. W. CATHCART, M.B. Twelfth edition. 16mo, 323 pages. Illustrated. Chas. Griffin & Co., Ltd., London.

DISEASES OF THE SKIN. By MALCOLM MORRIS. New edition. 12mo. 642 pages. Illustrated. W. T. Keener & Co., Chicago.

MODERN MICROSCOPY, A HAND BOOK FOR BEGINNERS AND STUDENTS. By M. I. CROSS and MARTIN J. COLE. Third edition. 8vo, 292 pages. Illustrated. W. T. Keener & Co., Chicago.

DISEASES OF THE URINARY ORGANS, INCLUDING DIABETES MELLITUS AND INSIPIDUS. By CLIFFORD MITCHELL, M.D. 8vo, 716 pages. Illustrated. Boericke & Tafel, Philadelphia, Pa. Price, $4.00 net.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY, FOURTEENTH SESSION. By WALTER LESTER CARR, M.D 8vo, 310 pages. Illustrated.

TRANSACTIONS OF THE TWENTY-FIFTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION at Washington, D. C., 1903. 8vo, 292 pages. Illustrated.

NOSE AND THROAT WORK FOR THE GENERAL PRACTITIONER. By GEORGE L. RICHARDS, M.D. 8vo. 330 pages. Illustrated. International Journal of Surgery Company, New York. Price, $2.00.

ADENO-MYOME DES UTERUS. By THOMAS S. CULLER. 4to, 91 pages. Illustrated. August Hirschwald, Berlin, Germany.

FUNCTIONAL DIAGNOSIS OF KIDNEY DISEASE WITH SPECIAL REFERENCE TO RENAL SURGERY. By Drs. LEOPOLD CASPER and PAUL F. RICHTER. 8 vo, 233 pages. P. Blakiston's Son & Co., Philadelphia. Price, $1.50 net.

MEDICINISCHER LAGER-KATALOG, No. IV. INNERE MEDICIN. Hirschwaldschen Buchhandlung, Berlin.

THE PRINCIPLES AND PRACTICE OF HYDROTHERAPY, A GUIDE TO THE APPLICATION OF WATER IN DISEASE. By SIMON BARUCH, M.D. Second edition. 8vo, 296 pages. Illustrate. William Wood & Co., New York. Price, muslin, $4.00 net.

# Book Reviews.

A Textbook on the Practice of Medicine. Designed for the Use of Students. By James Magoffin French, M.D., Lecturer on the Theory and Practice of Medicine, Medical College of Ohio; Attending Physician St. Mary's Hospital; Consulting Physician St. Francis' Hospital for Incurables, Cincinnati. Illustrated by Ten Full-page Plates and Fifty Wood Engravings New York: William Wood & Co, 1903.

This is a book out of the ordinary, in that it modestly professes to be only for the use of students and lays no claim to be a guide for practitioners. That it is well adapted to fulfil its professed object one is bound to confess, for its style is simple and suited to the comprehension of one who is only beginning his medical life, and is not yet familiar with the difficult language of his future profession; the definitions are clear and expressed in terms of easy comprehension, and each subject is treated of from the standpoint of one who knows the needs of the beginner, of the student who has everything to learn, and not from the superior level of the scientist who assumes that his readers are versed in all but the very highest branches, and who often, therefore, writes above the intellectual grasp of those who would learn from him. But withal, this is not a child's book. The language is simple and the style is lucid, but the teaching is sound and comprehensive; the book is up to date, and includes not only a statement of the facts of medicine, but also a presentation of the most acceptable theories. It seems to us, therefore, equally adapted to the uses of the practitioner, who has not the time or the inclination to study the larger treatises, but who wants the latest teaching on any particular subject in the fewest words.

The first fifty pages of the book are given to an introduction into the first principles of medical science, or a sort of running dictionary in which all the frequently recurring terms are defined and explained. In this part also the various morbid processes are described—fever, inflammation, degeneration, regeneration, etc., and a general statement is presented of the action of bacteria in the causation of disease.

In Part II, which constitutes the main portion of the work, the author presents a systematic treatise on the practice of medicine, describing under the usual heads of etiology, morbid anatomy, symptoms, treatment, etc., all of the ordinary and many of the rarer diseases which the physician may be called upon to treat, and of which the student must have knowledge in order to fit himself for the practice of his profession.

The book closes with a section describing the usual methods of clinical examination, including formulas for the reagents and test solutions employed in examination of the urine, stomach contents, blood, etc. Finally a very complete index facilitates reference to any subject treated of in the work.

Students generally will find this a most serviceable textbook and one which will admirably supplement the teaching received in their didactic and clinical courses. Practitioners also, especially those who have been too busy to follow closely the rapid advances of modern medicine, will find in these pages all that is needed to familiarize them with the latest accepted teachings of their science.

Die Gonorrhoe des Mannes und Ihre Komplikationen. Von Hans Wossidlo, Berlin: Otto Enslein, 1903.

In this work the author, as in his previous book on stricture, avows himself a firm partisan of the dilatation treatment in chronic gonorrhœa, as first laid down by Oberländer. And also, as does Oberländer, Wossidlo urges the need of urethroscopy to furnish an intelligent guide for the treatment of chronic urethral disease. The book is singularly free from extensive theoretical considerations, which so often encumber German practical works; its language, moreover, in its terse sentences not only reveals the author to be an English scholar, but makes his work the more acceptable to those whose German is acquired. In this book Wossidlo covers the most modern methods of gonorrhœal therapeutics in a decidedly practical form. Forty-four illustrations in the text well depict the essentials, while the most important lessons in urethroscopy are imparted by twenty-four superb chromolithographs. These were made from originals done in oil by the author's former assistant, Dr. Schramm, and will be welcomed by all who hitherto have had to content themselves with mainly schematic representations, or under colored or overcolored tints. The tone in which the book is written will make it valued primarily by the large number of American, English, and colonial physicians who have taken courses at the author's "Poliklinik." It will bring him to mind "wie er leibt und lebt," simple, unaffected, non-polemical, but always practical and convincing. These same qualities, evident in every line of this book will create favor for it among all those who must contend with the intricacies of this disease, from uncomplicated anterior gonorrhœa to its most serious and remote complications and sequelæ.

The American Illustrated Medical Dictionary. A New and Complete Dictionary of the Terms Used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, and the Kindred Branches, with Their Pronunciation, Derivation, and Definition, Including Much Collateral Information of an Encyclopedic Character. By W. A. Newman Dorland, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania Hospital; Editor of the American Pocket Medical Dictionary; Fellow of the American Academy of Medicine. Third edition. Revised and enlarged. Philadelphia, New York, London: W. B. Saunders & Company, 1903.

In this edition of Dorland's excellent dictionary new matter has been added to bring the book up to date and keep it in line with the constant multiplication of medical terms. Some of the tables, the least commendable feature of the work, have also been enlarged. We do not notice any addition to the illustrations To those who know this work, no words of commendation are needed; to those who do not, it will suffice to say that the book is a very serviceable one, owing to its comparatively small size, flexible binding, and clear type. The worst quarrel we have with it is on account of the numerous tables which we consider no addition to a dictionary. If they must be used they should be placed in an appendix where they can be consulted by the curious, but whence they cannot come to thrust their unwelcome presence in the face of the man who is looking for the definition of a word and not for a treatise on anatomy or chemistry or bacteriology. However, it seems to be the fashion with dictionary-makers to use them. In all other respects this dictionary is most commendable.

A Laboratory Guide in Urinalysis and Toxicology. By R. A. Witthaus, M.D., Professor of Chemistry, Physics, and Toxicology in the Medical Department of Cornell University. Fifth edition. New York: William Wood & Co., 1903.

A book which has reached its fifth edition hardly needs a very extended notice. The one under review is well named a "laboratory guide," for every page smacks of the laboratory and of the practical side of analysis. It is, however, much more than a mere guide to uranalysis, for the first forty-five pages present a fairly extensive course in inorganic analysis, and the last twenty-seven pages treat of toxicology. Having learned, practically, the meaning of chemical analysis, the student is successively taught qualitative and quantitative analysis of the urine, and the analysis of urinary deposits and calculi. Accuracy is the watchword throughout, and so rigorously is everything excluded which cannot come up to the high standard set by the trained analytical chemist, that the clinician will look in vain for several of his familiar methods. The instruction is so clear and explicit that "he who runs may read," a fact which is, perhaps, nowhere better shown than in the apparently trite subject of the heat and nitric-acid test for albumin; indeed, the perusal of these few short paragraphs would well repay many a well-informed physician.

Eye Symptoms as Aids in Diagnosis. By Edward Magennis, M.D., D. P. H., late Clinical Assistant at the Royal London Ophthalmic Hospital; Author of "The Eyesight of School Children," "Hygiene in the Schoolroom," "Healthy House Sites," "The Irish Poor Law System," etc. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co., 1903.

In this little book the author has gathered into easily accessible form a presentation of whatever there is for the general practitioner to learn regarding systemic as well as local diseases from a careful observation of the special symptoms connected with the eye itself. Nothing is at times more puzzling than to determine to one's own satisfaction the precise morbid condition present in a special case, and however great may be one's knowledge derived from reading as well as from experience, atypical cases will constantly present themselves, the new features and irregular symptoms of which will baffle the most skilful interpreter of morbid signs. The need, therefore, of taking advantage of every aid in arriving at a correct diagnosis is apparent. The eye does not reflect every morbid process going on in the body, but it does betray many, and the accessibility of this organ and the transparency of most of its structures make a study of it, as the author says, both interesting and satisfactory. This is a very small book, almost a "vest pocket" edition of about one hundred pages, but the author possesses the art of condensation without sacrifice of lucidity, and he has succeeded in compressing much useful information within its compass.

# Society Reports.

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-third Annual Meeting, Held at York, September 22, 23, and 24, 1903.*

**Special Report to the Medical Record.**

(Continued from page 600.)

*Thursday, September 24—Third Day.*

**Registration and Disinfection in Pulmonary Consumption.**—Dr. THOMAS J. MAYS in this paper said that consumption, instead of decreasing, had really increased in most of our large cities. He collected statistics which gave the death rate of consumption and pneumonia in twenty large cities and two states, representing a total of nearly thirteen million inhabitants, and in many instances covering a period of thirty years. Twenty-five charts were arranged from the data. In summing up the main points of this paper it appeared clear that in the prevention localities the phthisis rate fell, while the pneumonia rate rose, and that on the contrary, in the non-prevention localities the phthisis rate maintained itself above that of pneumonia; that in eight out of the thirteen prevention localities there had been a total increase of 80 per cent. of phthisis during the last five years, and that hence we might safely conclude that registration and disinfection have not thus far been shown to be of service in combating consumption.

**The Prevention of Tuberculosis.**—Dr. LAWRENCE F. FLICK, in speaking upon this subject, said that in studying the statistics of tuberculosis it must be remembered that in the last five or ten years laboratories had been opened in nearly all large cities and light had been concentrated upon tuberculosis, pneumonia, and bronchitis in such a way that better diagnosis could be made, and that consequently there had been a decrease in some nomenclature and an increase in others. In certain cities there had been increasing pneumonia, but a wiping out of the nomenclature of bronchitis and nearly so of the nomenclature of convulsions. In other words, many deaths accorded to bronchitis, inanition, etc., were now recorded strictly under the tables they should be, because there was a clear diagnosis of tuberculosis and not of pneumonia or of bronchitis. The introduction of preventable measures, the author stated, had always been followed by a decrease in the death rate. This was notably demonstrated in New York City, where the best scientific measures had been employed. Dr. Flick advised the establishment of sanatoria for incipient cases, every one of which he says was curable, and hospitals for advanced cases (or when this was impossible there should be an isolated ward in the general hospital), and dispensaries for walking patients, who by the exigencies of life are compelled to earn their own living. They could there be treated and instructed, and so rendered harmless to others. Dr. Flick emphasized the fact that the family physician should go into details in instructing his patient, and even have the patient repeat such instructions so that there could be no mistake.

**The Specific Treatment of Tuberculosis.**—Dr. MAZYCK R. RAVENEL of Philadelphia reviewed the attempts made within the last twenty years to discover a specific against tuberculosis, none of which had been proven to be entirely successful. At the present time all other methods had given way to the rational one of producing artificial immunity against tuberculosis in animals, and employing the antibodies thus brought into being for the treatment of man. While this was generally conceded to be the only practicable method, there was much difference of opinion among workers as to the details of procedure. The speaker mentioned also the bacteriolytic immunity, which was much more complex. This was usually produced by inoculation with living germs which had been attenuated in virulence by the action of heat or antiseptics, or by long cultivation on artificial culture media. With the absolute demonstration of the possibility of immunization of animals against the most virulent type of tubercle bacillus known, came the conviction that the immunization of man must follow at no distant day.

**Traumatism as an Etiological Factor in Phthisis Pulmonalis.**—Dr. WILLIAM T. ENGLISH of Pittsburg directed attention in this paper to some of the etiological factors of phthisis pulmonalis. He believed that passive predisposition was often rendered active by the intervention of traumatism, and said that traumatism of the chest had the power to produce phthisis pulmonalis, or to make more favorable the soil for tubercular deposit. The author emphatically declared that it was unfair to withhold sick benefits and remuneration for accident from those who developed phthisis pulmonalis after injury. Out of 128 cases of injury followed by traumatic pneumonia the writer found that about 63 per cent. were associated with fracture.

**Malignant Diseases of the Lungs.**—Dr. J. C. LANGE of Pittsburg read this paper. He reported four cases in detail. One marked feature presented was the occurrence of disability, anæmia, and loss of weight, accompanied by a peculiar color of the patients many months before the advent of any sign of lung disease. It would appear, therefore, that a tumor in the chest might have its origin and grow to a considerable size without symptoms indicating chest disease to the patient. The pleurisies were dry without effusions, and the scanty fluid consisted of bloody serum which, unfortunately, was not examined microscopically. The physical signs in the cases differed. When a limited pneumonitis surrounded the tumor the usual signs of hepatization were obtained, provided they were not obscured by other adventitious sounds. Carnification and atelectasis, present to a greater or lesser degree, as shown by autopsy, could not be made out by physical examination. Bronchial breathing, voice, and whisper, increased fremitus, and crepitant and subcrepitant râles were not obtained. The one characteristic pulmonary physical sign was that obtained by percussion. There was demonstrated by the percussion stroke an extreme solidity of the underlying tissue. So appreciable was this that the dulness of hepatization and the flatness of effusion were immediately excluded. Bronchial breathing, voice, and whisper were absent in the area of flatness and fremitus.

**A Fatal Case of Chorea Complicated by Endocarditis, Pericarditis, and Nephritis.**—Dr. AUGUSTUS A. ESHNER read a paper by this title. The patient was a girl ten years old, with a family history of rheumatism and chorea, who presented choreic movements in the upper and in one lower extremity, and later in the face, together with pain at one wrist-joint, as well as blowing systolic murmur at the apex of the heart. The temperature was elevated, the pulse accelerated, and pallor was marked. The urine became turbid and high colored, and albumin and tube casts were present. Later, a to-and-fro friction murmur became audible over the body of the heart and at its base. Improvement in the movements occurred under treatment, but a violent exacerbation succeeded upon a fright, and symptoms suggestive of uræmia appeared. Improvement again ensued, but in the eighth week death took place, apparently as a result of heart failure due to myocarditis.

**Family Periodic Paralysis.**—Dr. GEORGE E. HOLTZAPPLE of York gave a brief history of this affection as he had seen it in a family extending along some branches through a period of four generations. His observations had been made during the last twenty years. The characteristic symptoms and clinical phenomena of the cases heretofore reported by European and American observers are similar to those characterizing Dr. Holtzapple's cases. Of the family of which the author wrote, a number had died in an attack. The attacks as observed in his cases were minutely described. Their duration might be from

a few hours to, in rare instances, three full days. Improvement might be abrupt or require even a half day. The author believed that a post-mortem examination would reveal much that would explain the pathology of the disease. Thus far, this had not been obtainable in his cases. Dr. Holtzapple regarded the condition as a vasomotor neurosis affecting the blood supply to the anterior horns, which are almost wholly supplied by the anterior spinal artery. The paralysis appealed to him as closely allied to the paralysis occurring in migraine or hemicrania, such as oculomotor paralysis, aphonia, and paralysis of one extremity or of one-half of the body. Believing that the attacks of hemicrania and paralysis in this family had a common cause and assuming that both conditions were a vasomotor neurosis, large doses of bromide of potassium with caffeine were used. This seemed to give relief.

**A Case of Cerebral Thrombosis with a Skiagraph Showing the Area of Softening.**—This paper was presented by Drs. CHARLES W. BURR and C. E. PFAHLER of Philadelphia, and read by Dr. Burr. The patient was a woman sixty-seven years of age, who had had a stroke thirty years before, resulting in a right-sided hemiplegia and aphasia. The case was interesting, because, though she had complete motor aphasia, word blindness and agraphia, word deafness was not complete. The auditory speech center, however, was completely destroyed. There was some word deafness. Dr. Pfahler had made a skiagraph post-mortem, having replaced the brain for the purpose. The picture showed well the normal contents of the skull and the area of softening. Stress was laid upon the fact that in interpreting skiagraphs little dependence could be placed upon the results, unless the normal structures came out well. If they failed to be shown, appearances seemingly abnormal might be so or not. The value of skiagraphy in the differential diagnosis of hemorrhage and thrombosis from hemiplegia occurring in uræmia without any gross cerebral lesion was considered.

**An Investigation of Certain of the Reflexes and Sensory Phenomena and the Condition of the Eye-grounds.**—Dr. THEODORE DILLER of Pittsburg presented a paper with this title. The inquiries were among those forming part of the investigation in cases of nervous diseases. The author had examined 103 healthy young men whose ages averaged twenty-two years. In no case was the knee-jerk absent; but it was difficult to elicit in twenty-one instances. The Achilles jerk (35 tests) was found to be prompt in 28 cases and slow in 7; absent in none. The conjunctival reflex and pharyngeal reflex were found to be very uncertain, faint, or absent in more than half the cases. The average size of the pupil was found to be 2.76 mm. and the average range of excursion of the pupil in the light reflex was found to be 1.39 mm. In 43 of 98 cases tested, the range of excursion was 1 mm. or less. The average excursion of the pupil in accommodation is 0.967 mm. It was absent in three cases, sluggish or slight in range in 24. No marked differences in the size of the pupils were noted. In 13 cases marked cupping of the optic nerve was discovered; and in two or three instances this was suggestive of beginning gray atrophy. Stereognostic, muscular, and spacing senses were found pretty uniformly to be normal. Dr. Diller suggested that the actual size of the pupils in millimeters, both in light and in shade, should constitute a part of a neurologic record.

**Differential Diagnosis between Friedreich's Disease and Insular Sclerosis.**—Dr. F. SAVARY PEARCE read a paper by this title. The paper was prefaced by the general statement of the importance of diagnosis in its relation to all scientific therapeutics. The importance of incipient signs of disease was emphasized, especially those that may be confusing in differentiation between functional and organic diseases. There was no hope expressed that early diagnosis of the two diseases under consideration would lead to more successful treatment of these maladies. Dr. Pearce said that the form of Friedreich's disease that might be confused with insular sclerosis was the cerebellar or Marie type, wherein the cardinal symptoms of the more usual form were in some measure wanting. This form occurred after puberty; choreiform movements were very pronounced. Increased reflexes and clonus were frequent. Clubfoot and scoliosis were exceptional, and optic atrophy was common. Insular sclerosis might occur in several of the family, and it began, as a rule, between the ages of twenty and thirty. The gait might be spastic, cerebellospastic, or cerebellar. In the latter type would occur the confusing case; but the occurrence of rigidity with nystagmus, staccato speech, and intention tremor would aid in diagnosis, even though the reflexes were normal or diminished.

**Inflammation of the Middle Ear in Diseases of Children.**—Dr. THEODORE J. ELTERICH of Allegheny in a paper by this title spoke of the important relationship of inflammation of the middle ear to various diseases of infancy, and said there were but few children who had not suffered from otitis. That inflammation of the middle ear does not always manifest itself by a discharge from the ear is a circumstance which tends to obscure its existence and frequently prevents diagnosis. The author considered it an imperative duty of the physician to examine the ears of young babies suffering from diseases even apparently trivial in character. An instance was quoted of an infant seen by the writer, who had an attack of acute nasopharyngeal catarrh followed by catarrhal enteritis. There were no symptoms calling attention to the ears, but examination revealed a double otitis media. In cases of acute lobar pneumonia involving the apices of the lungs, middle-ear inflammation was very apt to be present. Otitis media was considered also an important and frequent complication of influenza. In measles it was observed generally in the form of an acute catarrh.

**The Result of One Year's Medical Treatment of Gastroptosis.**—This paper was contributed by Drs. J. DUTTON STEELE and ALBERT P. FRANCINE, and read by Dr. Steele. The paper embraces the work of three years in the medical dispensary of the University of Pennsylvania. Thirty cases have been observed for an average period of somewhat over fourteen months, with particular reference to the following points: (1) In what proportion of cases presenting signs of gastric indigestion, and in which gastroptosis has been demonstrated, are the symptoms due to downward displacement of the stomach? (2) Does long-continued mechanical support permanently restore the stomach to its normal position? (3) What is the prognosis of the condition? The answer to the first question was that in about one-fifth of the cases no cause could be found for the symptoms of gastric indigestion except gastroptosis. All of these patients improved greatly and were now practically free from symptoms. The treatment consisted in regulation of the diet, mechanical support with occasional doses of hydrochloride acid, and lavage at intervals. In the other four-fifths of the cases symptoms of gastric disorder could be distinctly traced to neurasthenia, gastric-motor insufficiency and dilatation, chronic constipation, or passive congestion of the stomach. It was considered that gastroptosis in these cases was probably a link in the vicious circle. The second question was answered in the negative. In all of the cases examined after a year of constant mechanical support the stomach was in exactly the same position as when first examined. In those cases in which the gastric symptoms were caused by uncomplicated downward displacement of the stomach the results had been very gratifying. The fight was a long one, but all the patients of this character were practically free from symptoms after one year.

**Edebohl's Operation of Decapsulation of the Kidney for the Cure of Chronic Bright's Disease, and the Indications for Its Performance.**—Dr. JAMES TYSON in this paper said that although the treatment of the various forms of

nephritis by operation had come to be known as Edebohl's operation, there could be no doubt that the idea of this method of cure suggested itself also to Reginald Harrison as far back as 1895. A résumé was given of Edebohl's cases. Reference was also made to the work of Dr. David Newman of Glasgow. Dr. Tyson's experience with the operation was limited to one case. It had been of a kind to satisfy him that the operation was at least life-prolonging in many cases and curative in some, and that it might even be extended to other cases than those of nephritis in its various forms. The case referred to was reported in detail. The patient was a girl of nine years who had had scarlet fever at the age of four. Immediately after the fever she had had no dropsy, but one year later and four years before admission to the hospital, she presented symptoms of acute nephritis, including albuminuria and general anasarca, which responded promptly to treatment at a hospital in New York City. Subsequent to this she had had five relapses. The last relapse set in about two weeks before consultation with Dr. Tyson, when she had general anasarca, with ascites, albuminuria, and casts. Paracentesis abdominis was done repeatedly, with the removal of a clear watery liquid, and so persistently did the ascites return that some concurrent cirrhosis of the liver was suspected. Medical treatment seemed unavailing, and operation was performed by Dr. Charles H. Frazier, January 11, 1903, the right kidney only being decapsulated. The immediate effect of the operation was astonishing. Two months later the left kidney was decapsulated. Four days after the operation the albumin measured one-sixth volume, with hyaline, and pale granular casts. In less than three weeks the patient was allowed to get up, but almost immediately the albumin increased to one-half volume, and she was promptly returned to bed. Since that time the patient had again been allowed to get up and had remained free from dropsy, and was the picture of health. Dr. Tyson said that it could not be asserted that there had been a cure, and that it was impossible to say that there would be. On the other hand, there could be no doubt that the patient's life had been prolonged. Apart from the urinary evidences she was seemingly in perfect health. The patient was last seen September 23, 1903. There remained one-third volume of albumin and a few hyaline casts in the urine. Dr. Tyson assumed that the operation should not be done until the usual medical measures of treatment had been thoroughly applied. Yet the operation should not be deferred until the patient was moribund. He believed cases of parenchymatous nephritis more favorable for operation than those of interstitial nephritis, since there was not so much actual destruction of vessels as compression. It was not reasonable to expect such satisfactory results where there were extensive cardiovascular changes. A further application of the operation was in obstinate so-called idiopathic hæmaturia. The speaker was encouraged to advise the operation in this condition, since it was not a dangerous one in the hands of a competent surgeon.

**Treatment of Suppurating Ulcers of the Cornea** was the title of a paper read by Dr. LEWIS H. TAYLOR of Wilkes Barre. He said that many of these cases were caused by an injury being maltreated or entirely neglected to be treated for some time after its occurrence, and frequently infected by unclean bandages which the patient has applied to the eye. The treatment should consist of strict cleanliness, flushing the eye with boric acid or mild bichloride solution and atropine, provided the eye is seen before suppuration sets in. If the ulcer is small, curretting and the application of silver nitrate, with perfect cleanliness and the use by the patient at home of atropine may be sufficient, but if the suppuration is extensive the galvanic cautery is the most efficient remedy. An ointment of the yellow oxide of mercury in vaselin is valuable as an aid to the healing. Tincture of iodine he felt was much more painful than the galvanic cautery, and its use was not recommended.

**Affections of the Eye Associated with Diseases of the Contiguous Sinuses.**—Dr. SAMUEL D. RISLEY of Philadelphia read this paper, in which he directed attention to the important relations which often exist between certain forms of serious eye disease and the inflammations of the lining membranes of the bony sinuses of the anterior portion of the skull, which is obvious when the close anatomical relation which they bear to the orbit, especially the maxillary antrum and the frontal and ethmoidal sinuses. He felt that the importance and frequency of such migratory inflammations or of congestions of the uveal tract of the eye causing severe asthenopia, associated with sinusitis, had been too frequently overlooked. Even in the presence of sufficient refractive error to cause the trouble, the failure to secure relief may be due to the co-existence of a chronic and unrecognized sinusitis or to a blocking or partial closure of the exit for the normal secretions of a continuous sinus by abnormal states of the nasal passages.

**The Operative Treatment of Strabismus** was the title of a paper read by Dr. WENDELL REBER of Philadelphia, who stated that he believed the following conditions should be carefully considered before deciding upon operation: (*a*) hereditary influence; (*b*) condition of refraction; (*c*) degree of deviation; (*d*) age; (*e*) visual acuity; (*f*) status of fusion faculty; (*g*) outward swing of visual axis. He referred to the investigations of Holthouse and Worth as showing that heredity influenced about 50 per cent. of the cases. Operation was deemed inadvisable before the tenth year, as in a family in which the tendency of the visual axis after puberty is toward divergence, the strabismus would frequently be very nearly corrected, and if an operation had been done prior to this time there would have been an over-divergence. The relative merits of tenotomy and advancement were considered, and the view expressed that tenotomy was performed as frequently as it is mainly on account of its simplicity, but the author believed that while this might be sufficient for low-grade deviations re-section of the conjunctiva and capsule offered the best prospects in high-grade deviations. He stated that he preferred the operation of Worth, which he described in detail.

**The Differential Diagnosis of Exophthalmos** was the title of a paper read by Dr. JOSEPH E. WILLETS of Pittsburg, in which he said that while the diagnosis of the condition *per se* was an easy matter, the diagnosis of the cause which was essential before deciding upon treatment was a difficult matter. Graves's disease was usually easy of diagnosis, although in some cases the exophthalmos was absent, in which event Von Graefe's symptoms might be either absent or present. The course of the disease was usually chronic, but instances were reported in which the disease had developed in a single night. Innervation lay at the root of the disease, and the sympathetic was the part of which the function was disturbed, and there was dilatation of the vessels in the region supplied by the carotids, which dilatation was responsible for the production of the exophthalmos. Certain conditions, such as hernia cerebri, might exist in the orbit, and produce the exophthalmos. This condition was liable to be confused with dermoid cysts, the important differentiating points being as follows: (1) A meningocele is immovably attached to the bone; (2) a tumor of this kind shows the pulsatory and respiratory oscillations which are communicated to it from the brain; (3) a meningocele may be diminished in size by pressure with the fingers; and (4) in order to be perfectly certain an exploratory puncture of the cyst must be made. Orbital aneurysm may closely resemble orbital cellulitis, and a valuable feature in the differential diagnosis is that pressure of the carotid on the same side as the aneurysm will diminish the pulsation and sounds present or cause them to disappear altogether.

**The Upper Respiratory Tract.**—Dr. J. B. McALLISTER of Ridgeway urged upon the general practitioner the importance of carefully treating any impairment of any of the functions of the nose, which, if neglected, may cause serious results. He stated that every case of hay-fever which had come under his observation had been primarily a surgical one, presenting such nasal defects as hypertrophied turbinates, deviated septi, spurs or ridges, or an exceedingly narrow space between the antero-superior part of the triangular cartilage and the outer wall of the nose. He referred at some length to the treatment of adenoids, enlarged tonsils, and other nasal conditions, and particularly to the condition caused by mouth-breathing in children, in consequence of which the nasal canal fails to develop.

**The Syphilitic Nose and Throat.**—This paper was read by Dr. CHARLES P. GRAYSON of Philadelphia. In it he called attention to the extreme suffering that is occasioned in some instances when the syphilitic lesion, either primary or secondary, attacks the nose, mouth, or throat. The diagnosis when the disease attacks the tonsils is particularly apt to be overlooked. He reported two cases of this character. He urged the necessity of radical treatment of this condition, not only to prevent the impairment of the features, but also the destruction of internal tissues. In regard to the treatment of these cases, he believed that but few of them had been sufficiently mercurialized during the early stages of the disease, and therefore recommended the combined treatment, either in the form of inunction or hypodermically, administration by the mouth being too slow. Locally, all the dead and as much of the hopelessly diseased tissue as possible should be removed by means of the forceps and curette and the application of peroxide of hydrogen.

**Some of the More Unusual Results of Movable Kidney.**—Dr. CHARLES P. NOBLE emphasized the fact that the usual result of undue movability and displacement of the kidneys was the production of reflex and nervous symptoms, but that exceptionally the kidney itself was seriously compromised. He reported cases of Dietel's crisis with acute hydronephrosis, due to torsion of the movable kidney; cases of hæmaturia, due to torsion of the kidney with interferenee with the return circulation through the renal veins; cases in which such local symptoms as the presence of a movable tumor appreciable to the patient, and weight or dragging in the region of the kidney, were the result of traction of the movable kidney upon its vessels or nerves, or upon adjacent structures He emphasized the fact that while the majority of cases of movable kidney required no treatment, in the minority the presence of reflex symptoms so disturbed the patient's health, that nephrorrhaphy was indicated upon relative grounds; that the indication was absolute when such changes took place in the kidney itself as were detailed in the present communication.

**The Treatment of Puerperal Sepsis.**—This paper was read by Dr. E. E. MONTGOMERY of Philadelphia. He directed attention to the importance of differentiating between germicidal infection and the results of putrid intoxication, as in the latter condition removal of the offending matter is usually followed by rapid recovery. The treatment must depend upon an accurate knowledge of the course and progress of the disease. If the disease had not extended beyond the uterus, hysterectomy would in all probability remove the cause of the disease, but there was great difficulty in distinguishing in which such a condition exists. Intravenous injections of formalin, 1 to 5,000, or of sublimate or of 1 per cent. saline solution, had proven beneficial. Antistreptococcic serum had not proven especially effective in the author's hands. The patient should be carefully watched during the progress of the disease, should be kept clean, the action of the kidneys and bowels should be stimulated, vaginal douches of saline solution, formalin, or sublimate might be employed, and high temperatnre should be arrested by cold applications.

**One Year's Work in Appendicitis.**—Dr. JOHN B. DEAVER of Philadelphia reported that during the year from September 1, 1902, to September 1, 1903, he had operated on 566 cases of appendicitis, with a mortality of 5 per cent. He divided the cases into three classes: (1) Those cases in which there was general or diffused peritonitis, in which the mortality was 31 per cent.; 16 cases being operated upon, and five proving fatal. (2) Cases in which an abscess was present, localized and usually filling the right iliac fossa, pelvis or both, and in many instances extending up to the liver; the latter organ has been found ulcerated. The appendix was also perforated and necrotic and often gangrenous. He operated on 183 cases of this class, with 22 deaths, or 12 per cent. mortality. (3) Cases in which the disease was confined to the appendix with stricture ulceration and sometimes necrosis of the mucous membrane. In many cases pus was found in the appendix after its removal. In some instances a small area of adhesive peritonitis was present outside the appendix, but no pus. In many cases the appendix was densely imbedded in organized exudate. He operated on 367 cases in this class, with 3 deaths, or 0.8 per cent. mortality. In conclusion, he stated that he believed early operation was the only treatment that would reduce the mortality in acute appendicitis to an insignificant figure

**Differences in the Management of Appendicitis and of Salpingitis.**—Dr. GEORGE ERETY SHOEMAKER of Philadelphia said that the differential diagnosis between appendicitis and salpingitis was of importance because there were important differences in prognosis. It might be impossible when the two organs lay in contact, but the distinction could usually be made from examination combined with the history. The prognosis was much better without operation in the case of tubal disease. When leakage of pus occurred from the tube a limiting wall of inflammatory material had almost always anticipated the event and diffuse peritonitis was most rare. The contrary was too often the case in appendicitis. Mild cases of appendicitis would rarely require operation if it were only possible to be sure that they would continue to be of the innocent type, and that after the fourth or fifth day the conditions would not suddenly become grave. The treachery of the appendix was a strong inducement to operate promptly on all except the simplest catarrhal cases in their first attack; upon these unless sure subsidence of symptoms occurred within twenty-four hours of the onset; and upon all when there had been a previous attack. When the tube alone was involved a much greater latitude was allowed for conservatism. The onset of pus formation could with safety be awaited; while in a considerable number, not of the severer type, the interests of the patient were best served by awaiting the subsidence of acute symptoms before radical operation. Complete resolution might occur in puerperal infections in a most surprising way, and early cases might be managed without sacrifice of tissue through the posterior vaginal incision. In appendicitis treatment by drainage without removal was undesirable; while some forms of salpingitis, especially streptococcus infections of puerperal origin, were most safely treated by vaginal drainage. Bad pus tubes, especially if gonorrhœal, bore radical operation better than extensive suppurations due to appendicitis. The principles of operation were the same, and consisted in walling off with gauze, gentle removal of the pus with gauze, removal of diseased parts, drainage in tube cases whenever the integrity of bowel wall had been invaded, in appendicitis whenever pus outside the appendix, rupture or gangrene had appeared.

**The Value of the Differential and Absolute Leucocyte Count in Cases Simulating Appendicitis,** was the title of a paper read by Dr. A. BARR SNIVELY of Waynesboro. He said that in inflammatory intraabdominal conditions

which warranted exploration, a differential estimation of the leucocytes would show the polymorphonuclear neutrophile forms increased in number and the eosinophiles greatly diminished in number. Diagnosis could not, of course, be made upon this examination alone, but the data were valuable in conjunction with the clinical findings. Here, however, two important factors must be taken into consideration in estimating the value of the leucocyte count: (1) severity of the infection, and (2) resistance of the individual. Among the diseases in which this leucocyte count was of value in differentiation were typhoid fever, intestinal obstructions, painful menstruation, pneumonia, amœbic dysentery, and movable kidney.

**The Treatment of Suppurative Appendicitis.**—Dr. Ernest Laplace of Philadelphia said that every case of fatal appendicitis comprised three distinct pathological conditions, viz., appendicitis proper, peritonitis, toxæmia. When operated upon in the stage of appendicitis proper, the mortality should be practically *nil*. Abscesses of the appendix are tuberculous, saprogenic or staphylococcic. The tuberculous abscess should be treated by incision, packing and drainage, without necessarily looking for the appendix. An abscess from a gangrenous appendix should be opened only after the peritoneal cavity had been carefully protected by isolating with gauze pads. The appendix is removed, the cavity of the abscess sterilized and scraped, then packed with gauze, which should be removed no earlier than seventy-two hours afterward. An infection of the peritoneum outside the abscess must be distinguished from a mere irritation by the transuding toxins from the abscess. The latter had little importance; the infection was likely to continue after the operation and result in a general peritonitis later. This therefore should be treated with the same caution and on the same principles as general peritonitis. Eventration and prolonged irrigation with normal saline solution offered the most rational direct treatment for checking the peritoneal infection. This might be continued after the operation for seventy-two hours by inserting a rubber tube in the right and left hypochondriac region, also a tube at the top and bottom of the abdominal incision. By connecting these various tubes in turn with the irrigator containing warm saline solution, a continuous irrigation might be obtained which would tend to check the local condition. Of course, this would not improve such cases as were already in a condition of toxæmia. These were practically hopeless. The laity, as well as the general profession, should be taught these facts, so that early operations, when the disease was strictly limited to the appendix, should be performed in every case.

**Perforating Gastric and Duodenal Ulcers.**—Dr. John H. Gibbon of Philadelphia read this paper, in which he called attention to the fact that it is now the generally accepted theory that when the condition is of long-standing, is accompanied by repeated hemorrhages uninfluenced by medical treatment, surgical intervention alone will give relief. Sudden onset of pain in the epigastrium, with boardlike rigidity of the abdomen and marked tenderness over the upper portion, accompanied by vomiting and prostration, should cause the surgeon to suspect a perforating ulcer and advise immediate operation, which is of the utmost importance. If previous history is positive, it will be of value as a diagnostic aid, but a negative history will not exclude the possibility of perforation, and if the condition is allowed to continue without operation general peritonitis will result. In the subacute perforations, the patient may present severe symptoms at first, but they abate instead of progressing as in the acute form, and the history and character of the initial symptoms are of the utmost importance in diagnosis and treatment. The pain incident to the beginning of menstruation and acute appendicitis may be conflicting factors with these conditions. Immediate operation, with repair of the perforation, thorough irrigation and drainage was outlined as the treatment, and a conservative procedure is a gastroenterostomy prior to the perforation in cases of chronic ulcer. Three cases were reported, two of the subacute variety and one of the acute class.

**Election of Officers.**—The following officers were elected for the ensuing year: *President*, Dr. William B. Ulrich, Chester; *Vice-Presidents*, Drs. Isaac C. Gable, York; P. Y. Eisenberg, Norristown; Fred. W. Coover, Harrisburg, William A. Marsh, Mount Pleasant; *Secretary*, Dr. Cyrus Lee Stevens, Athens; *Assistant Secretary*, Dr. Theodore B. Appel, Lancaster; *Treasurer*, Dr. George W. Wagoner, Johnstown. Pittsburg was selected as the place for the next annual meeting, and Dr. W. S. Foster of that city appointed Chairman of the Committee on Arrangements.

## MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*Second Semi-annual Meeting, Held in New York City, October 13 and 14, 1903.*

TUESDAY, OCTOBER 13—FIRST DAY.

The meeting was called to order, in the hall of the New York Academy of Medicine, by the President, Dr. A. T. Bristow of Brooklyn. He suggested the propriety, in the future, of holding the semi-annual meetings successively in other large cities of the State.

**Hepatic Drainage.**—Dr. J. B. Deaver of Philadelphia, Pa., read this paper. He said that the greatest difficulty would be encountered in interpreting the symptoms, both subjective and objective. An acute cholecystitis *per se* would, in the majority of cases, subside under appropriate medical treatment. When, however, the infection had extended upward into the hepatic duct there would be transient jaundice. While suppuration was infrequent as a sequela, calculi were rarely found in the hepatic ducts themselves. It was important to remember that the infection, not the gallstones, played the chief havoc with the patient. Suppuration of the bile passages might extend to the liver, leading, perhaps, eventually to the formation of multiple abscesses of the liver. Several cases were reported to illustrate the absolute necessity for removal of the obstruction and the establishment of hepatic drainage in addition to medical treatment. In this field, as in appendical surgery, he felt that many lives would be saved by early operation. He had never had occasion to regret resort to cholecystostomy, although sometimes he had regretted the performance of cholecystectomy. The adhesions caused by suture of the gallbladder to the abdominal wall were rarely a source of much inconvenience. If there were even a suspicion of infection of the liver, bile drainage was essential and must be free. He had never been convinced of the utility of hepatotomy except in a few cases of circumscribed abscess. The author drew the following conclusions: (1) Suppurative cholangeitis should be operated upon before the infection injured the liver cells, and before retained bile had had a chance to react injuriously upon the general organism. The presence or absence of gallstones was of no moment in deciding for early operation, although they were usually present. (2) Cholecystotomy was the operation of choice when the lesion was acute and the gallbladder had been functionating up to that time. (3) When there was calculous cholecystitis with obstruction of the cystic duct hepatic drainage was required, and especially when infection was present or suspected. (4) Whenever there is any doubt, he made it a rule to drain. (5) Abscess of the liver was prevented and pancreatitis relieved by such prompt drainage.

Dr. A. Van Der Veer of Albany thought cholecystectomy was an operation which should be approached with great caution. He fully agreed with the author as to drainage. He had been well satisfied with the results from posterior drainage down through the peritoneal pouch. The anxious cases were those in which gallstones were present in the hepatic duct.

Dr. George R. Fowler of Brooklyn remarked that a

live patient, even with an infected hepatic duct and with the possibility of its draining into the gall-bladder, was much better than a dead patient with a drained hepatic duct. To push the operation to the extent sometimes done in order to obtain direct drainage from the hepatic duct meant a tragedy; simply to drain from the gall-bladder itself meant, in the large majority of cases, a successful issue. While posterior drainage, from the mechanical standpoint, was the best, it was sometimes fraught with difficulty, especially in cases in which there were many adhesions posteriorly.

Dr. MAASS mentioned a case which had not been operated upon and which quickly terminated in death. A careful bacteriological examination post-mortem revealed pure cultures of the streptococcus in the cerebrospinal fluid and in the blood from the heart.

Dr. A. JACOBI of New York protested against contrasting "medical men" and "surgeons" in the way that had been done in the paper. He thought it was about time for over-specialization in this respect to stop.

Dr. Deaver, in closing the discussion, said that formerly posterior drainage had appealed to him, but in the cases in which he had tried it the results had not been encouraging. He would have to be very thoroughly convinced that the gall-bladder was thoroughly disorganized and highly infectious before he would attempt its removal.

**The Treatment of Certain Classes of the Underfed.**—Dr. W. S. ELY of Rochester was the author of this paper, and the class of cases he considered was those in which the patients were starving in the midst of plenty and who could be persuaded with difficulty to take sufficient nourishment. The best results were obtained from absolute rest and a diet of milk and raw eggs. One should begin with four to eight ounces of chocolate with two raw eggs alternately every two hours. At night, between the hours of nine and six, the interval should be lengthened to three hours. Patients soon became accustomed to being awakened at night and did not object to it. In many cases this course appeared to be necessary. The effort should be made to give in the twenty-four hours one quart each of chocolate and milk and six raw eggs. While admitting that many patients insisted that they could not manage milk, and were, indeed, managed by their stomachs, it was equally true that he had never seen, in this special class of underfed persons, one who could not be made to take milk with benefit. The person should be placed in a hospital under rigid discipline, and the mind should not be allowed to rule the stomach. Some individuals were in such abject slavery to their minds that they would be seasick and "throw up their staterooms" before they set sail. To offset the constipation induced by the diet mentioned, he gave from six to twenty tablets of rhubarb and soda daily and a morning enema. No gain should be expected in the first week, but if after the second week there was still no change the quantity of food should be gradually increased. It was to be expected that the tongue would be more or less coated during the treatment. An increase of from one to three pounds a week for ten or twelve weeks would usually be noted, and would be accompanied by improvement in the blood, the digestion and the general appearance. Increase in fat might not be especially desirable, nevertheless it must be looked upon as the best index of the good effect of the treatment. As soon as there was decided improvement, the patient might be allowed a little rare beef or some cereal, but it would be found usually that the pleasure anticipated from a return to solid food would not be realized. However, such treatment accomplished a vast deal of good, chiefly because it afforded the patient a convincing object lesson, driving home the truth that it was possible to take, and digest with benefit, a much larger quantity of food than the person had hitherto deemed possible or advisable. If the physician did not believe in the treatment, was afraid to persist in it because the tongue was a little coated or some distention was complained of, or if he were of the opinion that the stomach should be given long periods of rest each day, then he should not undertake this method of treatment, for it would surely fail.

Dr. EDWARD B. ANGELL of Rochester said that he had been studying, for the past two or three years, the blood-pressure in these underfed persons. Contrary to the statements usually found in the books, he had noted a marked reduction in the blood-pressure. In one case the pressure was only 50 mm., whereas the normal blood-pressure varied between 110 and 140 mm. He had formerly made use of the treatment outlined in the paper, but he now arranged the regimen so as to secure sufficient exercise, with consequent improvement in the oxygenation of the blood.

Dr. A. JACOBI said that he had noticed in a number of these patients that the heart was undersized.

Dr. EDWARD D. FISHER of New York thought the Weir-Mitchell method of treatment failed in many cases, and that it was well-nigh impossible to say beforehand which cases would, and which would not be benefited.

**Faculties of the Mind, Not Understood and Not Used, with Special Reference to the Curability of Epilepsy.**—Dr. M. A. VEEDER of Lyons read a paper with this title, in which he presented, at some length, certain theoretical considerations, particularly with regard to a systematic training of the mental faculties.

Dr. EDWARD D. FISHER said that while he believed every epileptic should be trained to some systematic idea of labor or occupation, the results, even under the most favorable circumstances, had been disappointing.

Dr. E. B. ANGELL thought an analysis of the paper would show that the author's efforts simply amounted to a change in our terminology. The good results in locomotor ataxia from Fraenkel's movements suggested what might be accomplished in epilepsy by properly directed muscular effort.

**Vaccination and the Law.**—Dr. NELSON G. RICHMOND of Fredonia was the author of this paper. He said that it had been held by the courts that children could not be lawfully vaccinated without the consent of the parents, and also that unvaccinated children could not be admitted to the public schools. Much difficulty was experienced in interpreting the law in cases in which repeated vaccination proved unsuccessful, but the number of these cases of so-called "immunes" was steadily diminishing, and it was well known that successful vaccination not infrequently followed the fourth or fifth attempt, even though the previous efforts had failed. The speaker read a letter, which he had received from Dr. John Thompson of Edinburgh. In this the opinion was expressed that "the conscience clause" in English law had accomplished the object of its framers, *i. e.* had diminished the opposition to vaccination. Dr. Richmond thought if vaccination had not been made compulsory the opposition to it would have rapidly disappeared, just as had occurred with regard to the use of diphtheria antitoxin. He believed the time had come to consider seriously whether it was better to have the vaccination law enforced or introduce a "conscience clause."

Dr. A. JACOBI declared that he had the right as a citizen to demand that the State should protect him and his from smallpox by compelling his neighbors to be vaccinated.

**Otitic Serous Meningitis; Lumbar Puncture; Recovery.**—Dr. FRANCIS HUBER of New York reported this case. He said that 16 gm. of cerebrospinal fluid had been withdrawn by the first lumbar puncture, and the next day about half this quantity had been abstracted. Soon afterward decided improvement had been noted, and on the twenty-second day after the mastoid operation and the twentieth after the last lumbar puncture, the child was practically well. Since this case had occurred he had found in the literature several similar cases reported by Schwarz of Halle, who was very much impressed with the value of the procedure. When the fluid withdrawn was

slightly opalescent it was very probable that a tuberculous meningitis complicated the otitis. In his own case no tubercle bacilli were found in the fluid.

Dr. JACOBI said that the case reported behaved like one of ordinary serous meningitis, and he was disposed to think there was no connection between the meningitis and the process in the mastoid. The improvement often noted in cases of meningitis after lumbar puncture led him to think that it might occasionally result in a cure, even in tuberculous meningitis.

**Symposium on the Röntgen Ray.**—This comprised the following papers:

**Therapeutic Use of the Röntgen Ray.**—Dr. A. D. BEVAN of Chicago presented this paper. He said that although at the outset he had been a pronounced skeptic regarding *x*-ray therapy, he had been deeply impressed at the apparently complete disappearance of nodules of carcinoma under the action of the *x*-ray. A recent interesting observation was that the combined use of the *x*-ray and of iodide internally proved very useful in blastomycetic dermatitis. Evidence regarding the effect of the *x*-ray in lupus was conflicting, but the preponderance of testimony seemed to be rather in favor of the Finsen treatment. The *x*-ray had been found to be an important, if not the most important, factor in the treatment of Hodgkin's disease. Although one observer had claimed to be able to cure 90 per cent. of cases of tuberculosis of the lymph nodes by means of the *x*-ray, his own results in this field had not been very encouraging. Some interesting results had been observed in cases of peritoneal tuberculosis. With regard to tuberculosis outside of lupus, he would say that *x*-ray therapy could only be said to be promising. The *x*-ray treatment of sarcomata had been most unsatisfactory. It should be remembered that sarcomata were essentially deep-seated growths; and it was now known that the *x*-ray had but little effect on carcinoma when deeply situated. The *x*-ray would destroy the epithelial cells of carcinoma superficially situated, as in epithelioma. The *x*-ray seemed to possess a selective action on the epithelial cells of epithelioma, probably owing to an abnormally low resistance in these cells. If situated within one centimeter of the surface the carcinomatous mass would melt down and be absorbed without causing necrosis. This result would usually be obtained with about twenty exposures made at intervals of one or two days. Cancer cells varied greatly in their resisting powers to the *x*-ray. The value of this therapeutic agent varied inversely with the size of the growth. At the present time it was difficult to answer the question as to whether or not the *x*-ray ever stimulated cancer cells to increased growth, but he had not himself observed any instance of such action. The Röntgen ray, then, was applicable to cases of slowly growing, very superficial cancer of the rodent ulcer type, especially those of wide extent—not depth—in which there was no regional involvement. The method was particularly applicable to growths about the lip and eyelid when removal by the knife would inevitably lead to deformity. In all other forms of carcinoma, in which the lesion was of rapid growth, or more deeply situated than the skin, or when limited to the skin and of considerable extent, the growth should be removed by the knife, and then the case should be subjected to a course of *x*-ray comprising about twenty exposures. He would say that at the present time the *x*-ray treatment of carcinoma had a very limited field. It was possible that the power of the Röntgen ray might be so increased as to enable one to reach the more deeply seated growths, or that some modification of the treatment might reduce the vitality of the cancer cells sufficiently to render them amenable to the action of the *x*-ray. It had occurred to him that possibly the use of iodine or arsenic might produce this effect upon the cells. The chief dangers of the *x*-ray treatment were: (1) Severe burning, and (2) the use of this agent in unsuitable cases, thus losing valuable time and greatly diminishing the chances of an ultimately good result from any method of treatment. Burns would occur occasionally even in the hands of the most careful and expert.

**Diagnostic Value of the Röntgen Ray.**—Dr. C. L. LEONARD of Philadelphia, Pa., presented this paper. He pointed out that clinical experience was of value in the employment of this, as of other methods of diagnosis. The use of the fluoroscope could never equal skiagraphy in the accuracy of its results, because it was largely influenced by the personal equation of the observer. Skiagraphy was especially valuable in connection with renal and ureteral calculus, leading to early and accurate diagnosis and the avoidance of exploratory operations. Of the 300 observations in this class of cases calculi had been found in 86, or over 28 per cent. In over 50 per cent. of the cases the calculi were in the ureter, and in 19 of these ureteral cases the calculi were passed after expectant treatment had been suggested as a result of the Röntgen ray examination. The negative diagnoses had been found fully as accurate as the positive ones. The total combined error, in both positive and negative diagnoses, was less than 3 per cent.—an accuracy which surpassed that of all other diagnostic procedures. The speaker said he employed in his work a self-regulating tube that would maintain the vacuum at the same point throughout the exposure. In most tubes of this kind the vacuum would rise an inch or more if the exposure were more than momentary, and this would lead to penetration of the calculus. If a low tube should be used, it should be capable of making both positive and negative diagnoses.

**Further Observations upon the Treatment of Sarcoma with the Röntgen Ray.**—Dr. W. B. COLEY of New York said that his experience coincided almost exactly with that of Dr. Bevan. Since February, 1902, he had had under observation at the General Memorial Hospital 103 cases of malignant tumors in which the *x*-ray had been used. Of this number, 30 were recurrent cancers of the breast, 42 were inoperable sarcomata, and 25 were superficial cancers of the head, face, and neck. In several cases, nodules, which had appeared after operations for cancer, and disappeared under the *x*-ray, had speedily returned in every instance. Of the 30 cases of recurrent cancer of the breast, in only a single instance had a large and deeply seated growth disappeared under the *x*-ray. The prophylactic value of the *x*-ray was a question of the greatest importance, but at present it could not be satisfactorily answered because of the many factors entering into the problem. Dr. Coley believed that there were good theoretical reasons for employing the *x*-ray for this purpose, yet he was compelled to admit that his own experience in this field had not given much support to this view. He believed a trial of the *x*-ray before operation was positively dangerous for two reasons, viz., (1) It blinded the patient to the real danger of the situation, and (2) it was apt to mislead the surgeon as to the true limits of the growth when operation was demanded. Only one year ago the statement had been made in this very room that 50 per cent of cases of cancer could be cured by the *x*-ray, and this method had been advocated as a substitution for operation. Again, Pusey, in his recent book, stated that 21 cases, or 77 per cent. were apparently cured, yet his final results showed that only 7 patients had gone beyond eight months, and only one case had gone beyond the fifteenth month. Dr. Coley said he believed that even in many epitheliomata of the face better results would follow excision.

Dr. GEORGE HOPKINS of Brooklyn said he had treated a sufficient number of cases of carcinoma of the breast by means of the *x*-ray to make him feel sure that, in the early stages, we possessed a cure for the majority of them in the *x*-ray alone.

Dr. W. E. FORD of Utica expressed the opinion that the *x*-ray did nothing more in cancer than delay its

growth. In their work at St. Luke's Hospital, Utica, they had absolutely failed with the *x*-ray in cancer of the cervix and body of the uterus, and only a temporary improvement and arrest of the growth had been noted in cancer of the breast.

Dr. A. VAN DER VEER thought most of those present would agree with Dr. Coley that permanently beneficial results were observed in only a small proportion of cases. He had been especially impressed with the great relief of pain afforded by the treatment.

Dr. LEE of Brooklyn cautioned against causing too rapid breaking down of the tumor.

Dr. L. DUNCAN BULKLEY of New York said that he was not quite so enthusiastic over this treatment as he had been a year ago, and he would not care to employ it in malignant diseases to the exclusion of other measures.

Dr. BEVAN said he believed Dr. McArthur and himself had been the first in this country to employ the *x*-ray for the detection of kidney stone, their observations in this field being published in 1898. He was satisfied that the *x*-ray could be depended upon to make a diagnosis of renal calculus in fully 90 per cent. of the cases if a proper method were employed. He made use of an enormous coil, a low vacuum tube, and a heavy lead shield on the abdomen. An aperture in this shield over the region of the kidney allowed the passage of the *x*-ray, and by excluding outside rays enabled the operator to secure better definition in the skiagraph. When such a skiagraph was placed before an aperture in a darkened room, so that only the plate was illuminated, and the observer viewed it, at a distance of 15 or 20 feet, through a good opera-glass, excellent definition was secured. One should not accept the result of such an examination unless at least one additional skiagraph confirms the findings in the first skiagraph. It was a serious mistake to accept the interpretation of such a plate as given by a non-medical *x*-ray expert—a fact which was confirmed by the amusing instance in which such an "expert" informed the surgeon that the case under examination revealed the presence of a very large stone with a soft center, and it was subsequently discovered that the supposed calculus was a vaginal pessary.

Dr. LEONARD said that he used a plate 20 inches long, so as to cover the whole tract to be examined, and arranged the apparatus so as to avoid the superposition of the shadows of calculi upon the bones of the pelvis. As we had found in the *x*-ray an agent which produced retrograde changes in malignant growths, it was our duty to use this agent in addition to surgical operation.

Dr. COLEY thought it was most important to correct the prevailing impression that we could cure deeply seated cancer by means of the *x*-ray, for there was not a single authentic cure on record by the *x*-ray alone.

**Radium in Medicine.**—Dr. SAMUEL G. TRACY of New York read a portion of a paper on this subject. He said that radium was discovered in 1899. Pitchblende contained about 5 to 10 per cent. of it, while from 2,000 pounds of uranium only one pound of radium could be extracted. The cost of this quantity of radium was $2,700,000. The source of the heat and energy emanating from radium were a mystery to all scientists. If a tube containing radium were kept in the vest pocket for a few hours it would cause a severe burn of the skin underneath, but this powerful physiological effect would not become manifest for a number of days.

**The Legal Status of the Röntgen Ray.**—Hon. WILLIAM W. GOODRICH, Presiding Justice, Appellate Division, Supreme Court and Judicial District, presented an address on this topic. He stated that *x*-ray photographs had been admitted as evidence in several States. The first case of such admission had not been reported in the law books, but occurred in Colorado in 1896. Probably the leading case in this country was one occurring in Texas in September, 1897. The competency of such evidence depended upon the science, skill, experience, and intelligence of the party taking the picture and testifying with regard to it. Even when properly admitted it was not conclusive upon the jury, but must be weighed like other competent evidence. In 1901 the Massachusetts Supreme Court held that while the picture produced by the *x*-ray could not be verified as a true representation of the subject, in the same way as a picture made by a camera could be, yet it should be admitted as evidence if properly taken. There had been no discussion in our own State of the use of these photographs, but as early as November, 1897, a complete apparatus for the production of the *x*-ray was erected and operated before a jury in the Kings County Court House. As no objection was made to this by opposing counsel the question was not passed upon by the appellate courts. This, however, was further than any other State had gone.

### SPECIAL MEETING.

*Tuesday Evening, October 13, 1903.*

**The Unification of the Profession.**—A special meeting of the Medical Society of the State of New York was called for the evening of October 13, for the specific purpose of taking steps toward bringing about a union of the two State medical organizations. A good opportunity to secure a large and representative attendance was afforded by the fact that the semi-annual scientific meeting of the society was held on the same day.

The large hall of the New York Academy of Medicine was filled with an eager and expectant throng when, at exactly half-past eight o'clock, the gavel fell. If there were any present who feared the audience on this occasion might not be as truly representative as the important business to be transacted demanded, they must have had their fears quickly dispelled on seeing, not only the familiar faces of many eminent members of the local profession, but a goodly proportion of active workers and recognized leaders from distant parts of the State.

On calling the meeting to order, the President, Dr. A. T. BRISTOW of Brooklyn, said:

"*Gentlemen of the Medical Society of the State of New York:* Almost two years ago the Medical Society of the State of New York, acting upon the recommendation of the President, Dr. Henry L. Elsner, authorized the appointment of a committee for the purpose of promoting a union between the State society and the State association. On request of our society, the association appointed a similar committee. Meetings of the two committees were held from time to time until, in October, 1902, at tis annual meeting, the association adopted resolutions placing restrictions upon its committee from which it could not deviate. At this time, also, the uncertain condition of the Code of the American Medical Association rendered the position of our committee difficult, for no one seemed to know its exact status. The clause, which was so objectionable to the State society, remained unchanged. An additional obstacle was the request of the association that the two societies apply for a new charter. In the course of time, under the resolutions referred to, the committee of the association went out of existence.

"At the May meeting of the American Medical Association the clause of the old code, which had caused the division of many years ago, was stricken out entirely, and it was clearly stated that the new 'principles of ethics' were merely advisory, and not obligatory on State bodies.

"Your conference committee, recognizing the fact that a most serious obstacle to the wish for union had been swept aside, requested the association to name a new committee to the end that fresh efforts might be made to close the gap. Informal conferences developed the fact that a reasonable compromise could be obtained by which the wish of the association could be complied with, that some legal recognition be taken of the new order of things. without in any respect sacrificing the continuity of our charter.

"At a special meeting of the Council and Fellows of the

association, the resolutions were unanimously passed which were printed in the notice of this special meeting (MEDICAL RECORD, October 10, page 581), and a new committee was appointed.

"I ask you to notice that these resolutions contain but a single restriction, *i. e.* that the reorganized society shall be called The Medical Society of the State of New York. [Applause]. In all other respects the new committee of the association is absolutely untrammeled, and has been appointed with power.

"The request is made that your present committee be given similar power. This is the question which you are called upon to decide to-night. The association has reposed full trust and confidence in its committee for the purpose of furthering that union which, two years ago, The Medical Society of the State of New York expressed its anxiety to bring about.

"It now remains for the society, which made the original proposition looking toward peace, to say whether it will have peace and bring to a happy termination a conflict which has lasted almost a quarter of a century.

"I will ask Dr. Curtis to read the communication of the Association."

The Secretary then read the resolutions which have already been printed (MEDICAL RECORD, *Ibid.*). They were received with hearty applause.

Dr. D. B. ST. JOHN ROOSA then said:

"*Mr. President, and Fellow-Members:* As one of those who has lived long enough to see the beginning, and I hope will live long enough to see the ending of this controversy that has been carried on so long, I have the pleasure of offering the following resolution, which, I think, will have the vote of every member of The Medical Society of the State of New York:

"*Whereas*, The New York State Medical Association, at a recent special meeting, duly assembled, has, by unanimous vote, appointed a committee with full power to meet with the similar committee of the Medical Society of the State of New York to arrange for the unification of the two organizations under the corporate name of The Medical Society of the State of New York; Therefore, be it

"*Resolved*, That the committee of conference of the Medical Society of the State of New York, already appointed, be given power equal to, and commensurate with the powers recently granted the committee created by the New York State Medical Association for the purpose of unifying the two State Medical Societies into the Medical Society of the State of New York."

Dr. WILLIS G. MACDONALD of Albany said:

"*Mr. President and Gentlemen of the Medical Society of the State of New York*" I rise in my place to heartily second the preamble and resolution presented by that distinguished fellow of this society, Dr. Roosa. [Applause.] The Medical Society of the State of New York has seen many glorious occasions. There are numerous notable instances in its long history of value to the American medical profession—its notable relation to the very organization of the American Medical Association; its later relations in the discussion of the very subject matter which has separated us in the State of New York for so many years; its more intimate relations with the medical education and the adoption of a method in this State which has been the pattern of many others. Again, and perhaps the most notable occasion—the best work of this society—presents itself now on this occasion. It shows you, Mr. President, that the medical profession, besides being learned, is also great; it shows you, Mr. President, that physicians can forget their differences, and that we are no longer the by-word of the world; it shows you, Mr. President, that now we are able to agree and sit down together in unity; it shows you that with the carrying of this motion men are able to forget and to forgive; it shows you that it is possible for us at this time to so meet together that we can settle all of our differences upon a very easy and very beautiful plan. [Applause.]

"Gentlemen, this is the most delightful occasion which I have ever known in the history of the Medical Society of the State of New York, and, as I have already said to you, I leave it to you if it is not the most important in its entire history.

"Gentlemen, we stand at the beginning of the twentieth century—on the very threshhold of it—with all the progress that has gone before, with all the attainment in a science of the immediate past, only to look forward as the unified profession to our greater opportunities, and to the greater necessities and to the greater honors of the future.

"Mr. President, it is my pleasure to again second this resolution."

The President then read the resolution. It was adopted, without a dissenting vote, amid cheers and prolonged applause, and the adjournment of the meeting was followed by hand-shakings and general congratulations. Whatever may be the final outcome, no one who witnessed the unmistakable evidences of rejoicing and goodfellowship exhibited after the adjournment of this memorable meeting could fail to be impressed with the fact that many of the old contentions had become dead issues, and that the rank and file of the profession, at least, were weary of bickerings and petty politics, and anxiously awaited the time when they would be relieved from this thraldom and could follow untrammelled those lines which were more in keeping with the seriousness and dignity of their noble calling.

*Wednesday, October 14—Second Day.*

**The New York State Hospital for Incipient Tuberculosis.**—Dr. WILLIS G. MACDONALD of Albany gave a description of the present status of this hospital. He said that fortunately ever since the selection of the site there had been no differences of opinion among the members of the board of managers. The plan of construction marked a distinct departure from some of the well-recognized ideas of construction. This was considered to be a necessary step in view of the peculiar rigors of the Adirondack climate. All the advantages of the cottage plan had been retained through the use of a system of isolated apartments. The exposure was such that, on the shortest day in the year, the sun would strike the porch at 8.45 A.M. and would not leave the porch until 4.45 P.M. There was a room 40 x 44 feet with two additions, 18 x 20 feet, provided with a most important system of indirect heating and radiation in order to properly protect the patients during the severe winter. When the temperature often fell to 30° F. below zero. The base line of the hospital was 1,639 feet above the level of the sea. There was abundant sleeping space for 108 patients. The dining room was capable of seating comfortably 200 persons, and the kitchen was of proportionate size. The patients would be placed in single rooms until observation of temperature and general condition showed that it was proper to put them in small dormitories. When they had been sufficiently improved to take physical exercise, and were approaching the period when they could go home, they would be placed, for about nine months of the year, in tents or open barracks. There was a camp of one hundred one-story wooden buildings, but without any heating system. It was estimated that 160 to 180 patients could thus be accommodated, the necessary space during the severely cold months being secured, if need be, by stopping the reception of new patients. The hospital would cost $1,900 per patient, or a total of $212,000. Although this hospital was larger than the Adirondack Sanatorium, and its construction high class, the cost was less than half that of the sanatorium. The ventilation was carried on by a system of flues, containing high-pressure steam coils, and by the use of electric fans. The water supply was obtained from

the mountainside at a distance of two and one-quarter miles.

**Technique of Operations on the Tongue.**—Dr. R. H. M. DAWBARN of New York read this paper. He said that the operation of removal below the jaw seemed to be the only logical one, and it possessed the additional advantage that it was easy by this method to tie the superficial carotid. A large gland, which should always be removed, was situated at the bifurcation of the carotids. It was very frequently involved. The shock was in direct proportion to the blood loss. This ligation of the external carotid should be done before attacking the submaxillary triangle. The objection to this, that it was liable to be followed by secondary hemorrhage, had been shown by experience to be purely theoretical. The patient should be so placed as to prevent any fluids from the mouth from pouring into the larynx, trachea, or bronchi, thus guarding against one of the chief causes of death in these cases. After the operation no pillow should be placed under the patient's head. Feeding should be carried on chiefly by the rectum and by rubbing into the skin large quantities of oil. Later on, the stomach tube might be used. The author advised against the custom of packing the mouth with gauze, preferring to rub all raw surfaces with aristol.

Dr. A. T. BRISTOW of Brooklyn could not agree with the author regarding the ligation of the external carotid as the first step of the operation. He made it a routine practice to devote a week to preparatory treatment, which consisted in the removal of all decayed teeth and the frequent cleansing of the teeth. This treatment was an excellent prophylactic against *schluckpneumonie*.

Dr. A. A. VAN DER VEER of Albany did not approve of the author's suggestion as to postural treatment. It was his belief that the patient should be gotten out of bed as early as possible.

Dr. WILLIS G. MACDONALD of Albany did not think the postural method had a sound anatomical basis—indeed, his own experience was directly opposed to that of Dr. Dawbarn. He would ordinarily expect to have the patient out of bed the day after the operation.

Dr. A. ERNEST GALLANT of New York pointed out that unskilful anæsthetization was an important factor in the causation of post-operative pneumonia.

**Potable Waters.**—Dr. E. S. WILLARD of Watertown read this paper. He said that purity of water was tested principally by two methods: (1) Chemical and (2) biological. The first method determined the nature and amount of mineral and nitrogenous matter, and the second, the number and kind of organisms present. The latter was the more useful analysis of water for domestic purposes. Mountain springs probably afforded the purest and most wholesome potable water, but were usually too inaccessible for large cities. Deeply driven wells were always subject to contamination. The quality of the water obtained from the domestic cistern depended very largely upon the materials of which the cistern was constructed. If metal were used the cistern and pipe should be well coated with asphalt and paint. Cement was most commonly used and was subject only to the criticism that it hardened the water. The speaker was strongly of the opinion that the domestic still might often become a potent factor of sanitation in a community. There were two principal systems of filtration of water, the English and the American. The former was perhaps better known as the slow sand filtration. The American system made use of a rapid mechanical method, its special peculiarity being the use of a coagulum by which suspended matter was entangled and deposited upon the surface of the sand. This coagulum seemed to be a necessity, and while much had been said about the detrimental effect of alum upon the system, it should be remembered that no more alum need be used than can be decomposed and deposited upon the filter bed.

Dr. F. C. CURTIS of Albany said that if one took as a measure of the purity of the water supply the death rate fom typhoid fever, it would be found that very few cities in this country have a pure supply of water. Thus, even in New York city the mortality rate was 20 to 25 per 100,000 of the population. This was not a good showing, when London and some of the large cities of Europe had a rate of only 10 or 15. In his opinion, chemical infiltration was not desirable, because the mechanical filter was nothing more than a strainer, whereas by slow sand filtration not only was the water strained, but the pathogenic organisms were destroyed by exposure to the action of the nitrifying bacteria. Up to 1899 the death rate in Albany was never below 50, and had at times reached 120, yet immediately upon bringing the filtration plant into operation the rate was decidedly lowered, and since that time had not risen above 15 per 100,000, and had averaged much less.

**Conservation in Pelvic Infection.**—Dr. JOHN O. POLAK of Brooklyn presented this paper, which was based on an experience with 79 cases of acute pelvic infection. Of this number, 38 were gonorrheal, 30 were streptococcus infections, and 11 cases belonged to the class of mixed infections. The author made use of a modification of Pryor's iodine treatment. His experience fully confirmed the claims made for it by Dr. Pryor.

**Dosage. A Plea for Proper Medication.**—Dr. A. JACOBI presented a paper with this title, but for lack of time read only a portion of it, *i. e.* that part treating of digitalis.

**Digitalis.**—He said that after digitalis leaves had been kept for one year in a tight tin box he had examined them. They were quite green, and after having been moistened, closely resembled the fresh leaves even on microscopical examination; nevertheless, a physiological test proved that more than 50 per cent. of the effective substances had disappeared. A year ago, five milligrams of these leaves immobilized the heart of a medium-sized frog; at present, ten milligrams of the leaves when injected under the periosteum hardly produced that result in a small frog. When speedy and decisive action from digitalis was required, neither the powdered drug nor the infusion should be relied upon. The most active ingredient of digitalis was digitoxin. Digitalis should be collected in the month of July. Digitalin was not an alkaloid but a glucoside, and was of very uncertain strength. Ten times the dose recommended on theoretical grounds was too often absolutely inert. In chronic valvular disease of the heart, in chronic debility of the heart muscle, in chronic anæmia, and in other similar conditions, digitalis in doses equivalent to four to six grains daily might be given to adults for weeks and months with no cumulative action, and with only a steadying and strengthening effect.

**The Dispensary Treatment of Tuberculosis.**—Dr. J. W. BRANNAN of New York read this paper. He described the method about to be introduced into the city dispensaries. The dispensary was utilized for giving instruction to the tuberculous patients, a nurse was sent to the homes of the patients to see that these instructions were carried out, and proper food was provided. A hospital had been provided in which could be placed such dipensary patients as were suffering from fever and other active manifestations of the disease. It was absolutely necessary in this system to have physicians who were possessed of enthusiasm for this particular work.

Dr. JAMES A. MILLER of New York said that in this dispensary work the patients were provided with pocket sputum pouches made of paper costing only a cent a piece. These were destroyed after having been used twelve hours or less. The patients came to the dispensary every week, when their weight and general condition were noted, and once a month a thorough physical examination was made and recorded. There had been treated by this dispensary system 160 cases in the past

six months, and of this number forty-nine were at present engaged in active occupations. The cost of such a dispensary was not great. It had cost them $15 for the printed blanks and $10 per thousand for the sputum pouches. A competent nurse for such work could ordinarily be secured for $50 to $60 per month.

**The Causes and Prevention of Infant Mortality in Nurseries and Asylums.**—Dr. E. H. BARTLEY of Brooklyn read this paper. He estimated the death rate of children under two years of age in the institutions of Greater New York to be 64 per cent. Among the more important causes were inherited weakness, congenital or acquired diathesis, starvation, exposure and neglect, infectious and contagious diseases, overcrowding and improper diet. He considered isolation of children with diarrhœa and disinfection of their napkins very important points in the management of these cases. The exclusion of flies was important from a sanitary standpoint, or when this could be done the flies should be destroyed at intervals by sulphur fumigation. The speaker advocated having small wards not exceeding 2,000 cubic feet of space, preferably connecting so that two attendants could take care of the two wards. No caretaker should be expected to take care of more than two infants. Stress was laid upon the depression of the nervous system as an exciting cause of disease.

**A Modified Allis Ether Inhaler.**—Dr. A. F. ERDMANN of Brooklyn presented a simple modification of the Allis ether inhaler which he had found to overcome the difficulty experienced in renewing the charge of ether in the ordinary inhaler while the patient was in the Sim's position. The modification consisted in making a transverse slot in the rubber sheath over the side of the inhaler, about four inches long by one-fourth of an inch wide. He also makes use of a removable cap for the inhaler made of some impermeable material. The modified, in more elegant form, would soon be placed on the market.

**Symposium on Typhoid Fever.**—This comprised the following papers:

**A Logical Definition of Typhoid Fever.**—Dr. H. A. FAIRBAIRN of Brooklyn presented a paper with this title. He said that the type of clinical manifestation of typhoid fever depended upon the organ or organs in which the typhoid bacillus was focussed. In view of the nature of the disease, the more frequent employment of chemical and bacteriological tests must be insisted upon. Many errors arose from dwelling upon the clinical aspect alone. He would classify or define typhoid fever something after this fashion: Genus, disease; species, infection; property, toxæmia, with the differentia.

**Anomalies and Difficulties of Diagnosis in Typhoid Fever.**—Dr. HENRY L. ELSNER of Syracuse was the author of this paper. A case was mentioned in which, although the person was in good health, the Widal reaction was present eighteen years after an attack of typhoid fever. The invasion of the disease might be characterized by a prodromal period extending over several weeks, and this period might be afebrile. In other cases the prodromal period covered only three or four days, and was associated with diarrhœa, fever, and grave meningeal symptoms. After a few days there would be a sudden development of hyperpyrexia and delirium. Such severe cases usually terminated fatally in fourteen to seventeen days. The temperature was likely to be normal, or almost so, after the third week. In the Ithaca epidemic the prodromal period was usually short, and the symptoms of the first week were quite severe. Typhoid fever was a disease characterized by low arterial pressure, and a pulse of only about 100. In the first week the maximum arterial pressure in adults was only 130 to 140 mm.; in children the blood-pressure was correspondingly lower, being in children under six years rarely over 100 mm. In typhoid fever the blood-pressure was hardly ever high except in the presence of complications. A diagnosis of typhoid fever should never be based upon a dicrotic pulse and a typhoid condition, although a dicrotic pulse was frequently noted in typhoid fever. A tremulous condition of the tongue, with fibrillary twitching, he had learned to look upon as quite characteristic of the early stages of typhoid fever. The presence of repeated chilly sensations pointed rather strongly to some other infection than typhoid fever. Some physicians still believed that diarrhœa and intestinal symptoms were necessary for the diagnosis of typhoid fever, but in his own series of 110 cases diarrhœa had been present in only 84, and some had been constipated throughout. In 48 of the cases there was nose-bleed. According to his experience, young patients had larger spleens than adults suffering from typhoid fever. In only 8 of the cases had he failed to discover the eruption, and it usually appeared on the seventh or eighth day of the disease. At times only a very few spots had been present, and usually in unusual locations. There were few cases that did not show some changes in the sensorium, although quite a number presented a normal appearance during the daytime. All clinicians had been surprised at the recovery of patients who had presented symptoms which they had supposed pointed to intestinal perforation. Among the most difficult differential diagnoses to make in connection with typhoid fever was in cases of malignant endocarditis of the paratyphoid type. Profuse hemorrhage was unusual in malignant endocarditis, and it should be remembered that this form of endocarditis was a decidedly unusual complication of typhoid fever. Chills were frequently present in the early days of malignant endocarditis. A diagnosis of infantile typhoid was rarely made positive in the early days of the disease, and it was true that many cases went entirely unrecognized because physicians failed to appreciate the fact that infants sometimes suffered from this disease. Continued fever in a child without localized disease and with an enlarged spleen must lead to a suspicion of typhoid fever. Hurried respiration, with associated leucocytosis, in children or adults argued against typhoid fever. A continued fever in a child or adult following an injury, with or without chills, and the typhoid condition, must lead to a thorough blood examination. If leucocytosis were present, whether or not the spleen was enlarged, typhoid fever might be excluded. Sepsis, pyæmia, or endocardial infection must be considered. Ehrlich's reaction was of uncertain value, for, while it aroused suspicion, it could never take the place of such an exact test as the Widal reaction.

**The Management and Treatment of Typhoid Fever.**—Dr. EGBERT LEFEVRE of New York presented this paper. He said that milk was considered the orthodox food for typhoid patients; nevertheless it was necessary to consider whether it met all the requirements of a food for such sufferers. It should be noted that milk was coagulated in the stomach into masses of varying size and hardness, and that in typhoid fever perfect disintegration of these masses occurred with difficulty. As the feedings occurred at short intervals, there was not sufficient time for digestion to be completed, and hence the curds frequently reached the ileum. This fact could readily be demonstrated by an examination of the stools. Under an exclusive milk diet of 60 to 70 ounces a day the tools were larger and contained more undigested food than a mixed or semi-liquid diet containing the same amount of proteids, carbohydrates, and fats. The addition of lime water lessened the tendency to difficult digestion only to a slight degree. Experience had taught the necessity of withdrawing milk from the dietary for a longer or shorter period in the acute infections of the intestinal tract. Again, in other diseases when it was desired to feed the patient on milk it was customary to begin with a small quantity of milk and gradually increase this quantity as the patient's digestive apparatus became accustomed to it, but in typhoid fever the patient was given large quantities of milk so soon as the diagnosis

had been made. He was of the opinion that the profession generally had adopted the exclusive milk diet because of its very common use in hospitals, but there were certain reasons for its use there, which did not apply to private practice. The speaker went on to say that he had one invariable rule regarding the diet, *i.e.* that in the early weeks of typhoid fever nothing should be given to the patient that could not be passed through a fine wire sieve. Water, plan or acidulated with hydrochloric acid or a little lemoni or orange juice, was beneficial and grateful to the patient. It was well to vary the diet by giving coffee, cocoa, tea, kumyss, and junket. Sometimes it was desirable to give stale bread, which had to be grated and passed through a fine sieve. With the free use of such diet he had not observed so much distention of the abdomen as on an exclusive milk diet. Egg when combined with milk increased the difficulty of digestion. The yolk of egg stirred into bouillon or soup should be given only after the fever had subsided. The value of gelatin in typhoid fever had been underestimated but it lessened nitrogenous waste and protected the proteids of the body, thus conserving both nutrition and energy. It was of value by making the other food palatable. A cold jelly bouillon was particularly grateful to the patient. When there was free intestinal hemorrhage he had found gelatin more beneficial than ergot and other drugs. Half an ounce to an ounce of gelatin should be dissolved in a pint of water, and then given at short intervals in doses of from two to four ounces of the mixture. Dr. LeFevre insisted strongly upon the importance of thoroughly emptying the bowels at intervals, a procedure which would often speedily reduce the tympanites and toxæmia. A daily anema should be given as a routine measure. Among appropriate purgatives were such saline as phosphates of sodium and the sulphate of magnesium, or. preferably, small doses of castor oil just sufficient to give one or two soft movements. When an intestinal disinfectant was indicated, five grains of salol might be added to each capsule of castor oil. The degree of fever should not lead us to administer intestinal antiseptics, but rather the presence of stupor, delirium, respiratory and gastrointestinal disturbances and especially the condition of the urine. The routine use of the bath whenever the body temperature rose to 102 or 103° F. was rapidly falling into disuse, and it was rarely necessary to give more than three or four baths a day. In many cases in which a bath at a temperature of 75° F. caused a good deal of shock, better results would follow the use of warmer baths. When acetanilide and phenacetin were given in small doses they did not depress the heart, but, on the contrary, quieted the nervous system and greatly improved the patient's general condition. The consequent lowering of the temperature was of benefit in reducing body waste. The older clinicians still held quinine in high estimation, and looked upon it as "the fever food." After an initial dose of 15 grains had been given the antipyretic action could be maintained by giving five-grain doses every six hours. Strychnine was a remedy most commonly employed to combat the progressive weakening of the heart observed in typhoid fever, yet he wished to dissent most emphatically from the present routine use of heroic doses of this drug in the early stages of this disease. The drug should be held in reserve until the condition of the reflexes, both cardiac and spinal, showed that the disease had begun to affect the nerve centers, and it should then be given in doses which would just meet the indications. He was of the opinion that in typhoid fever alcohol certainly acted both as a stimulant and a food.

**The Ithaca Epidemic.**—Dr. L. COVILLE of Ithaca read this paper, illustrating it with lantern slides. He stated that in the first six months about 1,300 cases of typhoid fever developed, and that in the summer there were eighty additional cases arising from the infection of a broken well. The epidemic rose abruptly from the middle of January to about February 2, and then gradually subsided until the middle of March. During this period those who drank exclusively of artesian water escaped the disease. For nearly two years the people of Ithaca had been warned that the city water was unfit to drink without purification. For many years the residents had depended upon artesian water, filtered water, and other sources for their supply. There had been some cases of typhoid fever each fall for several years past, but most of them were imported typhoid cases. While in previous years the type of the disease had been exceedingly mild and had not generally responded to the Widal test, last winter the type of the disease suddenly became more virulent, and the new cases gave the Widal reaction. The statement had been made on good authority that there was no sickness in the colony of Italian laborers that camped upon the bed of Six-Mile Creek early in December. All of the cases presented a distinctive throat picture—the dull red throat so commonly seen in gouty subjects. Constipation was uniformly present throughout the disease. There were altogether seventy-nine deaths. Of nearly 300 patients seen by Dr. Coville, 150 agglutination tests were made, and in most of the cases the reaction was obtained between the third and tenth days. Often a positive Widal reaction was followed on succeeding days by a negative reaction. No plumbers working in connection with infected houses, and no employees in the sewers or at the pumping station apparently developed typhoid. The epidemic was remarkable because of the great variations obtained in the course of the disease, the relatively small number of relapses in the typical cases, the cyclic features, the absence of milk infection and the avoidance of the transmission of the disease by flies. The death rate had been much higher among the adolescent students than among the townspeople. Many who had had typhoid fever during the past two years contracted the disease again during this epidemic.

**The Lessons of the Ithaca Epidemic.**—Dr. GEORGE A. SOPER of the State Department of Health made some remarks on this topic. He said that it might as well be admitted that there were one hundred sources of infection of Six-Mile Creek. One of the most remarkable features of the epidemic was the fact that there had been ample notice of the danger. It was well known that even health authorities too commonly neglected danger signals. He believed the disease to have been transmitted in a considerable number of cases directly, because, for the most part, the nurses were ignorant of the principles of disinfection and of other preventive measures, particularly as regards food. There were upward of 1,300 privies in that little city, and many of them had been infected. The water from nearly every well in town was analyzed, and about 30 per cent. of these samples were pronounced poor or dangerously bad. It was remarkable that nothing whatever was done for a long time after the breaking out of the disease in epidemic form. The local board of health seemed powerless to bring the people to any united and effective action. Disinfectants were employed in such a way as to do nothing but harm. The people were drinking boiled water for the most part, but a large number, probably several thousand, people believed that the water supply of the city was not the cause of the epidemic, and continued to drink the water. One of the great difficulties encountered was in ascertaining where and when cases developed, for there was no system of reporting typhoid fever to the board of health. The question of responsibility for the epidemic, if it could be placed, would teach a lesson of the utmost value. At the beginning of the epidemic most of the citizens said that the water company was to blame; others blamed the local board of health, while the University thought it was released from responsibility in the matter because it was, so to speak, merely a guest in the city. Eventually the city was aroused from its lethargy and did all that was asked of it. The sum of $25,000 had been spent so far in suppressing

this epidemic, about $10,000 being expended by the State Board of Health, for the most part for laboratory work and the compilation of statistics A most important lesson from this epidemic was the need for the dissemination of information upon public and private hygiene

**The Epidemiology of Typhoid Fever.**—Dr. CYRUS W. FIELD 2d of New York read this paper. He said that the disease was chiefly disseminated in three ways: (1) By personal contamination; (2) by contamination of the water supply, and indirectly of milk, and (3) by means of household insects. Flies were probably a frequent mode of transmission. Ice cream might convey the disease if the milk used in its manufacture had not been cooked. It had been proved that the bacillus typhosus could live in ice for about five months, and that soiled clothing might remain a source of infection for two or three months, One should not forget that it was just as necessary to disinfect the urine as the stools, and that the infectious character of the urine should be borne in mind by physicians when examining the urine of typhoid-fever patients.

Dr. J. F. HEFFRON of Syracuse said that although it was an American physician who first differentiated typhoid from typhus fever, and although most of the additions to our knowledge of typhoid fever had been made by American physicians, we had certainly allowed the Europeans to outstrip us in the matter of securing and maintaining a pure water supply. Every one of our public sources of water supply was to-day practically infected, yet it was the duty of the State to protect the health of the people by preventing such contamination. The only protection was the installment of a competent purification plant in connection with every city water supply. It was also of the utmost importance that all sewage should be completely sterilized before allowing it to reach other sources of water supply. In these matters the medical profession had an important duty to perform with regard to the public.

He desired to commend most heartily the position taken by Dr. LeFevre with regard to a milk diet in typhoid fever. For the past two years in all of his own cases in which an intestinal antiseptic had been indicated he had employed acetozone. It was not very agreeable to take, but he could say unhesitatingly that he had never before used a so-called intestinal antiseptic of like efficacy.

Dr. A. JACOBI said that the urine should be examined for typhoid bacilli longer than the fæces, for not uncommonly the bacilli persisted in the urine many weeks after the person had apparently recovered from typhoid fever. He would take exception to LeFevre's advocacy of acetanilide, even in small doses, for the action of this drug was to convert the hæmoglobin into methæmoglobin and give rise to more or less marked cyanosis. Its action on the blood was as the toxic action of chlorate of potassium. Acetanilide was an anilin poison, and the most dangerous remedy of the group. It was true that phenacetin sometimes caused cyanosis, but this was very exceptional.

Dr. LEFEVRE replied that when two or three grains of acetanilide had been given in febrile conditions he had never seen any untoward result except in persons presenting an idiosyncrasy. Some years ago he had examined critically the blood of persons who were taking acetanilide, and except in a few cases no such destructive action on the hæmoglobin could be discovered. A satisfactory examination was not yet forthcoming for these exceptional cases. A little point of some practical importance was that when a well was found to be infected the further use of that water for drinking purposes could be effectually prevented by pouring in a gallon or two of petroleum.

---

**Fighting Typhoid Fever in Germany.**—A press despatch from Berlin states that the imperial budget for 1904, now in preparation, allots $37,500 for combating typhoid fever, which is specially virulent in Bavaria, Prussia, and Alsace-Lorraine. The contamination of the rivers is a frequent cause of the fever.—*Science.*

### PROSTATECTOMY AND GALVANOCAUSTIC PROSTATOTOMY (BOTTINI'S OPERATION): THEIR PRESENT STATUS IN THE RADICAL TREATMENT OF THE HYPERTROPHIED PROSTATE GLAND.*

BY WILLY MEYER, M.D.,
NEW YORK.

PROFESSOR OF SURGERY AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; ATTENDING SURGEON TO THE GERMAN AND NEW YORK SKIN AND CANCER HOSPITALS; CONSULTING SURGEON TO THE NEW YORK INFIRMARY.

THE question of the proper selection of operation for the relief of patients suffering from an enlarged prostate and its sequelæ has lost nothing in importance or intensity of interest. Castration, including vasectomy, prostatectomy and galvanocaustic prostatotomy (Bottini's operation) are still in the field. The relative value of these various procedures can be properly determined only by the final results—best by the results obtained by a single man in a fair series of cases. Personal extensive experience, unbiased observation and reports of late results based on objective examination are the factors that will advance the proper estimation of each procedure.

Castration, although it has completely and permanently restored many a prostatic's urinary affection, will not be discussed here. It still has staunch advocates among men whose views surely command respect. However, since we have two methods to help such patients by attacking the gland directly, indirect influencing should be relegated to the rear, or, at least, should be our very last resort, especially as it deprives the patient of his virile power. Personally, I believe that a direct attack should first be made in every case. Failing in this, an operation on the testicles or the vas deferens may then be resorted to. In accordance with this view of mine, I shall, therefore, here consider prostatectomy and galvanocaustic prostatotomy (Bottini's operation) alone.

That prostatectomy is the most radical as well as the most surgical procedure from an operative point of view, goes without saying. The operation is typical. It aims to remove the hypertrophied tissue within the prostatic capsule. If this be accomplished, proper urinary drainage ought to become re-established. Recurrence of the former trouble seems more than unlikely.

This is not the place to discuss the technique and the advantages or disadvantages of the suprapubic and perineal route, respectively. If the gland can be removed by operating from below, this procedure deserves the preference, were it for the sole reason that the wound which is made for shelling out the gland can be at the same time utilized for drainage. But aside of this, perineal prostatectomy has the advantage of permitting operation under the guidance of the operator's eyes. At the present time it certainly seems to be the consensus of opinion that perineal prostatectomy is the operation of choice in the surgical treatment of the enlarged prostate. Yet, such opinion, it seems to me, can be justified and of real value only if borne out by the results.

Surgeons everywhere are about to enlarge their experience in this direction. The near future will, no doubt, bring us the data so eagerly looked for. Death rate and late results, as well as possible sequelæ, are the main points to be taken into consideration in judging the va ue of the suprapubic and perineal operations. With regard to the death rate, personal statistics will again be of special value, as surgeons who perform the same operation time and again will soon master and improve necessary technical details and learn to avoid or to overcome troubles arising during the after-treatment.

With regard to the complications that may arise in connection with prostatectomy, the following may be mentioned: (*a*) the occurrence of uni- or bilateral epididymitis, also orchitis with abscess formation; (*b*) persistent perineal fistula (avoidable by improved technique); (*c*) dribbling, a feature which generally seems to be of a transitory character only[1]; (*d*) recurrence of some of the former symptoms, as, for example, residual urine, pain in urinating, frequency of micturition; (*e*) stricture (curable by sounding); (*f*) impotence. (See below.)

Galvanocaustic prostatotomy (Bottini's operation), on the other hand, does not attack the bulk of the gland; it only cuts grooves through the mass, leaving the gland itself in place. However, it must be remembered here that it is not the bulk of the gland that is the disturbing factor in the trouble under consideration. Keyes, senior, says:[2] "It is not the size of the prostate that makes it obstructive or causes it to yield subjective symptoms. Many a man with a very large prostate empties his bladder entirely, has no residual urine, and does not greatly complain, while another with practically no general enlargement but with a third lobe or a prominent bar—thus making his prostate actively obstructing—will suffer the torments of the damned, and embrace any operation and take any risk which promises to relieve him from his torture. It should therefore be the surgeon's object to remove the obstructing portion of the prostate rather than to take the organ away in bulk, since the bulk alone, generally, does little damage."

Bottini's operation, as a whole and in all its details, in contradistinction to prostatectomy, is by no means a typical operation. The number, length, direction, and depth of the cuts must differ, with every case. Numerous other questions, too, as for instance: Shall we hook and compress the prostate while ploughing through the same. Shall we repeat the incision, whole or in part, by going over the ground twice, shall we use blades of various size and length, how had we best proceed in the presence of a median lobe? etc., are still mooted ones. To do Bottini's operation properly, as required in the individual case is, therefore, often a very difficult task. To determine the various points at issue, it is necessary to make a careful examination of the patient with regard to size, configuration, and consistency of the gland if this be palpable per rectum; a thorough cystoscopic examination is essential in every case,

*Read before the American Surgical Association, May, 1903.

and sometimes may have to be repeated. In short, every single case has to be studied as to its requirements. If this be done, and if all the details of the operation be carried out properly, the result in trained hands is often surprisingly good.

The proper carrying out of Bottini's operation, then, has to be looked upon as a difficult procedure, involving considerable experience.

My purpose in writing this paper is *not*, to discuss the generally recognized value of the two excellent cutting operations at our disposal for prostatic enlargement, viz., suprapubic and perineal prostatectomy, but to prove from my own personal experience, that, in certain specially selected cases, in which prostatectomy by either route is contraindicated or refused by the patient or his relatives, Bottini's operation should be proposed, inasmuch as it, too, may not only relieve, but completely cure the prostatic trouble.

In order to test personally the merits and demerits of galvanocaustic prostatotomy, I made it a point, for five years, from October, 1897, to October, 1902, to practise Bottini's operation to the exclusion of others. No selection of cases was made. Regardless of statistics, the operation was done in every case of prostatic hypertrophy that came under my care.[3] Age, debilitated condition, complicating renal affection, were not considered contraindications. In not a single instance was the operation refused as long as the patient asked for it. In every one of the cases the after-treatment was carried out by myself personally; points of interest in the further history were carefully noted.

It stands to reason that by thus making no discrimination whatever, Bottini's operation was, in some instances, performed upon patients who, according to my present views, would have derived greater benefit from prostatectomy.

As regards the death rate, this too was naturally swelled by my not refusing the operation to men whose far-advanced bilateral, complicating renal affection, should have deterred me from making any attempt at still bringing relief. Further, I commenced this work "a pioneer" in the real sense of the word, having no other guide in the beginning than Bottini's original writings and Freudenberg's first brief, but excellent article, published in the *Berliner klinische Wochenschrift* in April, 1897. The instruments and batteries I used, too, were inferior to those now employed. The decrease in the death rate of the consecutive series (of twelve each) of my cases, nicely illustrates the gradual improvement in the necessary paraphernalia as well as technique and personal dexterity.

A step backward with regard to the death rate was made at the time I did Bottini's operation with the help of spinal anæsthesia, from October, 1900, to October, 1901, and was testing solutions of tropacocaine, sterilized in various manners. Two deaths, I think, were due to this method of anæsthetizing the patient, surely not to the operation as such.[4]

Within the five years mentioned, 59 patients were operated upon by me, their age ranging from 47 years to 80 years. Of these patients the operation was done once in 48, twice in 10, and three times in 1 patient (in all 71 operations). Fifty-two recovered and 7 died, death occurring as a direct consequence of operation in 3, viz., (1) acute sepsis, 30 hours after operation, a chronic septic, on account of bilateral far-advanced, pyelonephritis (MEDICAL RECORD, March 5, 1898, page 331); no autopsy. (2) Perforation of the bladder by anterior cut (case of suppuration of cavum Retzii). Post-mortem obtained. The anterior cut has since been abandoned as a routine measure (MEDICAL RECORD, May 12, 1900, page 799). (3) Embolic (?) pneumonia (case of advanced bilateral pyelonephritis.)

Indirectly, death was due to the operation in 2 cases: (1) Suprapubic cystotomy 8 days after operation (MEDICAL RECORD, January 14, 1899, page 42). In order not to appear biased, I shall count this case among the deaths directly due to the operation, thus raising the number of deaths directly due to the operation to 4. (2) Phlebitis of the left saphenous vein with following, probably embolic, pneumonia on the eleventh day after operation. No autopsy. (MEDICAL RECORD, May 12, 1900, page 805).

In the remaining 2 of the 7 fatal cases death resulted from the immediate effects of spinal anæsthesia with the sterilized solution of tropacocaine. The histories of these cases will be published in the near future.

Dividing my cases into series of 12 each and comparing the death rate in an ascending scale, we have:

| | Deaths directly due to operation. | Deaths indirectly due to operation. |
|---|---|---|
| In the first twelve.... | 2 | .. |
| " " second " .... | 1 | 1 |
| " " third " .... | 1 | .. |
| " " fourth " .... | .. | 5 |
| " " fifth (only 11 so far) .. | .. | .. |

Of the 52 patients who recovered from operation: 34 are alive to-day; 3 could not be traced; 3 died, within 6 to 10 weeks after operation, of pyelonephritis that had existed long before operation; 12 died from various causes, as apoplexy, cancer, general debility, nephritis, etc., from 9 months to 3 years after the operation.

Of these 52 cases 13 had complete retention, 33 had incomplete retention, and 6 had a persistent suprapubic fistula.

Of the 33 patients with incomplete retention 14 used the catheter from 1 to 6 times a day; 1 wore a urinal.

Of these 27 patients who had been using the catheter, viz., 13 with complete and 14 with incomplete retention, 18 got rid of the catheter permanently, 2 used it, mostly for convenience sake, once at night; 3 were still obliged to use it; of 4 the later condition could not be ascertained.

The patient who had worn the urinal put it aside soon after the operation.

Of the 6 patients with persistent suprapubic fistula 2 have remained permanently cured to date, fistula remaining closed two and three-quarter years and three and one-half years, respectively, after operation; in 2 the fistula closed temporarily, but broke open again one year and two and one-half years, respectively, later, coincident with the formation of a new stone; one died, after Bottini's operation performed by me (twice before by another surgeon), with a contracting fistula, ten weeks after operation, of pyelonephritis, which had existed prior to my operating; one, in whom the suprapubic fistula had persisted for ten years, was so much improved by the operation that, one year later (last written communication), he complained about his inability to introduce a No. 8 (French) silver catheter through the fistula, for the sake of irrigation, as he had been in the habit of doing for so many years. He died 2½ years later, after an attempt made by a surgeon, at his home, to close a recto-urethral fistula, brought about by the colleague who had done Bottini's operation twice before he came into my hands.

In 9 of the 52 patients with hypertrophy of the prostate, treated by means of Bottini's operation, I found the trouble associated with stone. In these

the presence of the stone was not determined before operation in one case; the stone was washed out before doing Bottini's operation in one; the stone was cut out by means of suprapubic cystotomy in one, persistent suprapubic fistula followed, permanently closed by means of Bottini's operation. The stone was removed by litholapaxy, in one case, which was followed by irritated bladder, necessitating suprapubic cystotomy; persistent fistula set in, which then was permanently cured by Bottini's operation. The stone was removed by litholapaxy, in one case, followed by Bottini's operation three weeks later to quiet the irritated gland; completely cured. The stone was removed by litholapaxy plus Bottini's operation at the same sitting in four cases. Three of the last four cases were described in detail in my article entitled "The Treatment of Prostatic Hypertrophy Associated with Stone in the Bladder, by Means of Litholapaxy and Bottini's Operation at One Sitting" (*Annals of Surgery*, July, 1902).

In 5 of the 52 cases the membranous urethra was accidentally injured, causing perineal abscess in 4, chronic inflammatory œdema of scrotum and penis in 1. These 4 patients, in every single instance, had a very soft gland, and every time the prostate had been well hugged by the beak of the incisor, as originally advised by Freudenberg and described in my last article. Furthermore, I did not at that time use an incisor with centimeter division on the shank. This scale on the shank (recent proposition of Freudenberg)[6] I consider a very important point, indeed. Just as the needle of the ampèremeter of the battery indicates the degree of heat of the invisible galvanocaustic knife as it ploughs its way through the obstructing mass, so these marks on the shank will show us whether or not the beak is still within the bladder. By this means we are enabled to control its proper apposition to the body of the gland. This scale on the shank is particularly indispensable in those cases—not infrequently met with—in which the palpating finger fails to feel a rectal tumor, although the cystoscope shows the presence of intravesical enlargement. If we do not drag the gland too much by forcibly pulling the instrument forward, the beak will stay in place and not slip into the prostatic urethra. These five perforations, followed by formation of a perineal abscess and inflammatory œdema, happened in my first 33 cases, and occurred entirely without my knowledge. Since that time I have taken care to avoid compressing the gland, and the accident has not occurred again. I now try to walk the golden middle-way. I hug the gland, pull gently, but do not compress it. It may be mentioned here, however, that all my patients in whom the accident happened recovered. One, classed as improved, died two years later, of acute cholecystitis and peritonitis, remaining improved as far as his former trouble was concerned, until death; one, is alive and remains improved to date; two others were cured and remain so up to date; the patient with inflammatory œdema is alive to-day (classed above as not improved; large hard gland, etc.).

My personal experience with these cases does not, therefore, bear out the statement recently made by E. L. Keyes, Jr., who says, in his valuable article on Bottini's operation,[7] that all the cases in which this accident happened have died. On the other hand, one thing is certain, namely, that this mishap—regrettable as it is at the time as well as annoying to both patient and surgeon—gives assurance that the division of the gland has been done thoroughly, provided the beak did not slip into the the prostatic urethra.

In one patient the rectum was injured and a recto-urethral fistula established. The accident happened in a much reduced man, seventy-one years of age, who had a small, soft prostate and far advanced suppurating bilateral pyelonephritis. In his case (the only time in the 71 operations done), for special reasons, the street current, without ampèremeter, was used on the strength of the electrician's assurance that the amount of current required could be gauged by the degree of noise produced by the apparatus. The fistula never gave the patient much trouble, except that the often occurring bubbling caused by gas passing from the rectum into the membranous urethra at the site of communication, annoyed him. He recovered from the effects of Bottini's operation. In course of the after-treatment bilateral nephrotomy with drainage had to be done, at various times, at either side large abscesses being evacuated, both kidneys having been entirely destroyed by the suppurating process. Death occurred eight weeks after operation.

In this case it would have been better to have left the patient to his fate. But his complaint of continued, intolerable burning pain at the neck of the bladder induced me to still make an attempt at relieving him.

Marked unilateral or bilateral epididymitis, as a direct sequel to Bottini's operation, was seen in six patients, and suppurating process of the testicle necessitating incision in two patients, necessitating castration in one patient. A unilateral suppurating process of the vas deferens after vasectomy in one.

A distinct cause for these complications cannot be stated; they were observed in cases in which the permanent catheter was left in place for some time, as well as in those in which this was not done. Patients in whom the permanent catheter was left *in situ* for more than four weeks did not develop this inflammation. It was also seen by other surgeons after prostatectomy, with or without catheterization and bladder irrigation, with or without sounding during the after-treatment. Other sequelæ of Bottini's operation, such as sepsis, pyæmia, and embolic pneumonia, I have not seen any more of late. Why not, I am unable to say. Many patients operated upon surely were in a deplorable general condition.

Another much-dreaded sequel, perforation of the bladder, can be avoided by exercising proper care in operating, omitting the anterior incision and filling the bladder with fluid or air.

In 20 of the 52 cases that ended in recovery the stream is noted as good at time of first examination; in 14 as fair; in 2 as weak; 32 had no pain in urinating; 5 had some pain in urinating; 1 had much pain in urinating.

This became changed in a few instances at later examinations.

As regards weight, this was noted in 38 of the surviving cases, and in every instance there was a gain, sometimes considerable.

I have also observed in some cases that even though the urinary trouble was not much relieved by the operation, the general condition of the patients became improved. Pre-existing constipation was incidentally overcome in the majority of cases.

With reference to curing the vesical catarrh, if present, I have so far not seen a single man with sufficient patience to keep up continued irrigation of the bladder as advised. Hence, quite a number present a more or less turbid urine. On the other hand, I count 5 or 6 patients whose urine cleared up absolutely after normal vesical drainage had once become re-established.

The [illegible] operations in the [illegible] were performed by the writer between the years 1894 and 1900 inclusive, in the practice of Bottini's operation for the cure of prostatic hypertrophy. Medical Record, May 5, 1900. It will be of interest to [illegible] results [illegible]—2½ years after [illegible] operation—was published in March-Apr., 1903.

Operations from March-Apr., 1900, showed the following:

| | |
|---|---|
| 24 cases | 30 operations in all. |
| 4 " each 2 operations | 8 " |
| 1 case 3 " | 3 " |
| 15 cases each 1 operation | 15 " |
| 24 cases. | 56 operations. |

Cured 9; final examination 3—25 months after operation. Much improved 7; final examination, 6 27 months after operation. Improved 2; final examination 12—19 months after operation. Died, 4 as a direct or indirect result of operation; 2 others died in acute of operation 6 and 10 weeks, respectively after the date of pyelonephritis of old standing.

Re-examination and correspondence with the surviving 18 of these 24 patients or their families, brings out the following late results in March-April, 1903:

Of the 9 patients reported as cured in 1900, 1 was reported dead, the end having come as a result of intense anæmia, 5 months after operation, urination perfect up to death; 2 have died since 1900 of apoplexy and of cholecystitis and peritonitis, the former having remained fully cured as to his urinary trouble up to his death in the fall, 1902, 4½ years after operation. One case had to be classed as improved at the time of the patient's death. One was not heard from.

Of the remaining 5, 3 have remained absolutely cured and are in splendid condition to-day.[8] One patient had a persistent fistula after suprapubic lithotomy, permanently closed by Bottini's operation (see above). One is in almost the same condition as before operation—large hard prostate with median lobe; two operations; long-continued post-operative retention. Here prostatectomy should have been done (see MEDICAL RECORD, May 12, 1900, page 803).[9] One has to be classed as much improved; had absolute retention before operation; got rid of catheter; urinated, in 1900, four or five times during the day, and once during the night; to-day, as per written communication, four or five times during the day, six times during the night.

Of the 7 cases reported as much improved in 1900, 3 died; 2 from causes not known, 1 from cancer of the axillary cavity following epithelioma of the finger. The bladder condition of 2 of the cases up to the time of death could not be ascertained; in one case it was worse than before, in part due to cachexia. One has not been heard from. Three are living to-day. Of these 3 patients 1 remained "much improved"; 1 is to be classed as "improved," the patient uses the catheter, for convenience sake, twice a day. In 1 the trouble recurred to some extent. This latter patient has no subjective trouble to-day; his urine is absolutely clear; he urinates from 5 to 6 times per day, nights twice, but the relation between voluntary micturition and residual urine is 200 : 450. Repeated cystoscopy points to a median lobe, which was divided by operation, the two halves seeming to act as a valve during urination. My advice to the patient has been, suprapubic cystotomy and prostatectomy through the same route, or, in case of his refusing prostatectomy, suprapubic cystotomy for the removal of the divided median lobe, and placing the [illegible] of the [illegible] in position under the guid[illegible] of my eye. There is no prostatic enlarge[illegible] present.

Of the 2 patients reported as "improved" [illegible] 1901 [illegible] died of pneumonia after much suff[illegible] from a chronic bone disease, incidental [illegible] wasting debility and cachexia in 1902; a p[illegible] the urinary trouble for which he had been ope[illegible] upon by me in October, 1898, had recurred [illegible] time before death. The other patient, a pronou[illegible] diabetic, 72 years of age, with a hard gla[illegible] enormous size, has, since 1902, relapsed int[illegible] same condition as prior to operation. He i[illegible] only one of my 55 patients operated up[illegible] times. At present his voluntary urination is [illegible] secured by a few drops; he again depends upo[illegible] catheter, which he uses 3 or 4 times i[illegible] hours. The only tangible benefit derived fro[illegible] operations done between January and April, [illegible] is the temporary relief he has had for a per[illegible] 3 years, in addition to greater ease of catheri[illegible] with reduced pain, up to the present time.

With my present experience, my choice i[illegible] case, if operation had been insisted upon, [illegible] have been perineal prostatectomy under [illegible] anæsthesia.

To summarize: 5 of the 9 patients repor[illegible] cured in April, 1900, are still living, and hav[illegible] either heard from or re-examined in 1903; of [illegible] 3 have remained cured; 1 has to be classed as [illegible] improved (recurrence of frequency of micti[illegible] during night); 1 not benefited (classed as cu[illegible] 1900, on basis of written communication);

Three of the 7 patients reported as "Muc[illegible] proved"[10] in April, 1900, are still living— [illegible] heard from or re-examined in 1903; and of th[illegible] remains much improved, 1 can be classed a[illegible] proved only to-day, 1 has recurrence of re[illegible] urine, commencing before 1900.

One of the 2 patients reported as improv[illegible] April, 1900, and still living, proves, on final exa[illegible] tion to be benefited to some extent only.

An analysis of the 34 patients who are ali[illegible] day and were either re-examined or heard fr[illegible] March-April, 1903, shows the following:

| | |
|---|---|
| To be classed as cured[11] | [illegible] |
| To be classed as improved | [illegible] |
| Recurrence to some extent (residual urine) | [illegible] |
| Former symptoms recurring after temporary cure o[illegible] relief, therefore to be classed as: Not improved | [illegible] |

Of the 18 patients classed as "improved" 5 w[illegible] benefited by the operation to such an extent t[illegible] according to former classification they would h[illegible] been called much improved. Another patient i[illegible] excellent condition at present and considers hims[illegible] cured, but is too recent to be classed as cured.

Of the 5 patients classed as "not improved" two had a hard, very large prostate. One [illegible] them should, according to present views, ha[illegible] been subjected to prostatectomy. In one the[illegible] was persistent suprapubic fistula after supr[illegible] pubic cystotomy in 1898 (55 stones remove[illegible] litholapaxy plus Bottini in 1900 on account of [illegible] curring stones; fistula closed and urination sat[illegible] factory for 2 years; 5 months ago suprapub[illegible] fistula reopened, most probably owing to recurren[illegible] of calculosis. Patient not seen again so far. [illegible] 1 there was persistent suprapubic fistula, closed [illegible] means of Bottini's operation in 1901; developme[illegible] of vesical calculus (phosphate)—fistula reopene[illegible] prostatectomy by another surgeon. One who w[illegible] tabic, had temporary relief, soon increase of residu[illegible] urine; suprapubic prostatectomy by anoth[illegible] surgeon.

Of the 10 patients cured to-day, 3 had complete retention (1 case, 3 days; 1, 2 weeks; 1, 3 months). 7 had incomplete retention; 3 of these had to use the catheter).

Of the 18 patients classed as improved 6 had complete retention from 10 days to 2½ years; 12 had incomplete retention, 3 using the catheter.

Of the 15 patients who had to use the catheter 10 laid the same permanently aside. Of the remaining 5, 2 use the same once or twice per day for the sake of having a longer interval of comfort, especially a better night's rest, 3, as per written communication, still need it.

To repeat: Of 15 patients that had been obliged to use the catheter 10 got rid of it permanently; 2 could, if necessary, get along without its aid; 3 are still in need of it.

In 7 of the 34 patients the prostatic trouble was complicated with vesical calculus. Two of these are cured of their stone as well as of their prostatic trouble; 5 got rid of the stone, and were improved as far as their prostatic disease is concerned; 2 patients will probably be classed as cured after a somewhat longer period of observation.

Little or no attention has so far been paid to the question as to whether Bottini's operation or prostatectomy interfere with the power of intercourse. It is true, this question is purely a social one, but may be of quite some importance if the patient have a wife living and he be still below 60 to 65 years, sometimes even if he be older. Thus, not long ago, this question was the point of preliminary discussion raised by the much younger wife of a gentleman 64 years of age, with complete retention. Bottini's operation was performed, voluntary micturition re-established and the power of intercourse fortunately preserved.

Inquiry of the 34 patients still living regarding this point brought out the following facts:

The cases of 2 of my patients cannot be utilized in this connection inasmuch as prostatectomy was performed by other surgeons some time after Bottini's operation had been done by me; in 3 cases present condition with regard to this point is not known; 1 patient, 73 years old, had no inclination for the last 15 years; 1 patient, 80 years old, was sick for years with paralysis agitans; 1 a diabetic, had absolute lack of erection for the last 9 years; 3 patients—2, 65 years, and 1, 71 years of age—have been impotent for the last 3 years or longer.

Deducting these 11 cases, we have 23 patients whose cases can be used with reference to the question at issue. Of these: The power of intercourse was preserved in 20, viz., in 7 of the 10 cases classed as cured, in 12 of the 18 cases classed as improved, in 1 in which the urinary trouble in part returned. In 1 of these patients, a man 52 years old, there is, however, no orgasm, in 1 there is no seminal discharge in spite of orgasm, in 1 power of intercourse is not interfered with, though both vasa deferentia were resected 5 years ago. Of course, ejaculation is missing.

The power of intercourse was more or less interfered with in 3, namely: A man, 49 years, is impotent since operation; he has emissions, erection, however, is absent; another, 62 years old, had weak erection before operation, is worse since operation; a third 71 years of age, claims to have lost the power of intercourse since operation.

Thus, Bottini's operation has produced impotence in 2 out of 23 cases, increased a weakness that had existed prior to operation, in one. In 2 other patients irregularities in the normal seminal discharge have appeared.

This question as to the power of intercourse should also be carefully noted when tabulating the late results of prostatectomy, perineal and suprapubic, a point which, as I have stated before, has thus far received but little attention. Loss of sexual power (erection) has certainly quite frequently been met with after enucleation of the gland.

It is not easy to explain this loss of sexual power (lack of erection) as a result of galvanocaustic prostatotomy or of prostatectomy.

Erection is a complex motor mechanism, and, as such, subject to nerve influence. The impulse starts from the psychic action of the cortex of the large cerebral hemispheres, or from the sensitive penile nerves. Both transmit it to the center of erection, which is situated in the lumbar portion of the cord.

From here the impulse is conveyed to the respective anatomical structures over two routes, viz., over the so-called nervi erigentes, representing the vasodilators of the arteria penis profunda, which feeds the corpora cavernosa; and, secondly, over the motor fibers for the ischio cavernosus and transversus perini profundus muscles. Both groups originate in the sacral plexus. These nerves run within the trunk of the common pudic nerve; the latter is situated so far laterally, that it cannot be reached during any of the operations mentioned. A direct injury to the same as a causative factor of following impotence can, therefore, be excluded. However, a number of its branches might suffer during the operation. Injury to the ejaculatory ducts, or the operation as such, may produce a relaxation of the normal anatomical condition of the veru montanum and the prostatic urethra, both necessary to induce proper reflex action for erection.

The lack of seminal discharge as a sequel to any one of these operations is attributable to direct injury to the ejaculatory ducts, or to a deviation of their course, or to a stricture of their lumen, both latter conditions resulting from the post-operative cicatrization around them. Its consequence is interference with normal ejaculation, or total sterility.

In perineal prostatectomy direct injury to the ducts can be avoided by bringing the field of operation into better view with the help of Syms' rubber retractor, or Young's metal retractor, or other mechanical devices brought out for this purpose.

Rydygier's intracapsular resection of the prostate, recently proposed (*Centralblatt für Chirurgie*, 1902, No. 41), would enable us still more surely to avoid the ducts. However, as that part of the prostate immediately surrounding the prostatic urethra is left untouched by the same, it is questionable whether it will prove sufficiently effective. Further experience will show the range of its usefulness.

Data regarding the point in question in connection with suprapubic prostatectomy are also absolutely necessary. *A priori* the high operation would seem to be more apt than the perineal one, to produce impotence, inasmuch as it is done in the dark. Still, at one of the recent discussions on prostatic surgery, a gentleman asserted that none of his prostatics operated upon suprapubically had shown loss of erection.

In Bottini's operation it may be possible to avoid injury to the ducts by making the direction of the lateral incisions at an angle nearer 90° than 45°, and by making the posterior incision directly within the median line.

A careful compilation of all cases operated upon, with notes as to the late results also in regard to this point, is required in order to determine which of the methods under consideration is most apt to be followed by impotence. Surely, such knowledge

would often materially influence the selection of the method of operating.

With regard to adding data of value to the question of the possible gonorrhœal origin of prostatic enlargement, so widely discussed of late. I regret that no careful record was kept by me as to this point. Still, in looking over the histories of my cases, I find the remark "no previous gonorrhœa" in seven cases.

Having in the foregoing statistically stated my personal results in a series of 59 cases, I would yet like to add the following general remarks:

*Nursing.*—In Bottini's operation the after-treatment sometimes requires a great deal of patience on the part of the patient as well as that of the attending surgeon. In many instances careful nursing of old, debilitated patients, and prompt intervention in the event of suddenly arising emergencies, are the main requisites in bringing a case to a successful issue. This accounts for the fact that ward patients so often prove to be more troublesome and less benefited by the operation than private patients who are under the immediate supervision of the surgeon or his permanent assistants.

*Filling of the Bladder.*—Every one of my 71 operations, with the exception of those done on the first 5, has been carried out with the bladder filled with water. The massiveness of the eschars so often observed to be pushed off the gland, prove the effectiveness of the operation, as far as the cauterization is concerned.

In the next 12 or 24 cases that may come under my care, it is my intention to do the operation with air distention of the viscus, and note results.

*Anæsthesia.*—To-day all my operations are again carried out under local anæsthesia, with 3 per cent. eucaine and a suggestive general anæsthesia with equal parts of alcohol and water; the latter during the time of cutting the grooves. Since I have ceased compressing the gland with the beak of the incisor, the local pain has been materially reduced. General anæsthesia is applied only upon the patient's specific desire.

*Chetwood's Modification of Bottini's Operation.*—The modification of Bottini's operation, proposed by Charles H. Chetwood of New York—median urethral section; digital exploration of prostate and introduction of a modified incisor through this wound, controlling the progress of the knife by rectal palpation—I have never tried. So far I did not feel the want of the preliminary median incision. I follow the principle of carrying out such a purely intravesical operation, as Bottini's operation, without adding this incision—the same as we do in litholapaxy—except it become necessary during after-treatment (abscess formation). Furthermore, it will sometimes require an unusually long finger to successfully palpate the intravesical surface of the gland; not infrequently such palpation must prove a technical impossibility—a fact, which has been mentioned by Chetwood. Drainage of the bladder with the permanent catheter introduced the entire length of the urethra has given me satisfactory results. Besides, the suggested modification requires general anæsthesia, and will often keep patients in bed longer than Bottini's operation does.

*Young's Modification of the Bottini-Freudenberg Incisor.*—The various sized blades of the galvanocaustic knife proposed by Hugh H. Young of Baltimore,[13] I have not tried as yet, but can well see their indication, based on the result of cystoscopic examination. I shall make use of it whenever indication arises.

*Litholapaxy and Bottini's Operation Done at the Same Sitting.*—In the course of this work I found that litholapaxy, hitherto almost always advised against in this class of patients, can well be done if combined with Bottini's operation at the same sitting. I recommended this combined operation in an article on the subject recently published in the *Annals of Surgery.*[14]

*Indication.*—Since October, 1902, I have tried to individualize with regard to advising the proper operation in every case that has come under my observation. I have done during that period perineal prostatectomy in 6 and Bottini's operation in 4 patients. I have tried to find indications for such individualization, but would not venture to formulate any definite points with regard to it so far. At present I would say that I now invariably recommend the cutting operation in patients with a large, hard gland, also in patients with a gland of medium consistency, if they seem to be able to stand the operation and general anæsthesia. If necessary, spinal anæsthesia is employed. I do so still more if a median lobe is present. I further advise prostatectomy in patients who are desirous of being relieved of their trouble in one sitting at all hazards.

If the gland be soft and compressible, particularly if not palpable per rectum, but the cystoscope has determined the correct diagnosis; if the patient be old and much run down by prolonged sickness, I advise Bottini's operation, making the patient or his relatives fully aware of what they may expect. At present it seems to me, that in cases in which the condition of the patient is such as to raise doubt as to whether he will be able to stand prostatectomy, Bottini's operation, as the least risky (though not void of dangers), should be recommended. The chances are that it will do the work. However, should the result not be satisfactory, experience has shown that it does not preclude the possibility of doing prostatectomy later, at a time when such patient may have recovered from his former precarious general condition.

In other words, I carefully consider all points in every case—anatomic, pathologic, and social—before I decide in favor of one of the two procedures under discussion.

A few cases for illustration:

A patient from out of town, a hard-working man, suffering from enlarged prostate associated with stone, came under my care. It was important to cure him, if possible, in one sitting. He had a very pronounced emphysema and chronic bronchitis. Perineal prostatectomy, with removal of the stone through the same incision if possible, was clearly indicated. The operation was done under spinal anæsthesia, with perfect success.

Another patient, in the sixties, with complete retention for the last 3 months, was brought to me on account of prostatic trouble with the statement that he, as well as his wife, were absolutely opposed to any cutting operation, and the patient was willing to continue the catheter throughout the remainder of his life, if nothing else could be done. Bottini's operation was proposed under these circumstances and performed soon after. About ten weeks later, upon inquiry regarding the patient's condition, he (being a German) writes: "I am famous" (famos), meaning that he is in excellent condition. The catheter had been laid aside.

A gentleman who had mining interests in the West, necessitating considerable traveling, wanted to have done the most radical work possible, so that no further work should be necessary. Perineal prostatectomy was proposed, accepted and performed. At the present time, five months later, he has not a drop of residual urine; now and then some little dribbling during the night. A slight contraction

at the neck of the bladder was overcome by sounding.

Another patient, above 60, had a large amount of residual urine due to an enlarged prostate. Prostatectomy was proposed and accepted. General examination of the patient before operation revealed pronounced valvular disease of the heart, so much so that, after consultation, general as well as spinal anæsthesia seemed contraindicated. Inasmuch as Bottini's operation can be and, in fact, ought to be carried out under local anæsthesia, that operation was proposed and done with much benefit to the patient.

Another patient still, 80 years of age, was brought to me suffering from a far-advanced paralysis agitans with contracted hip-joints and absolute retention. His widowed daughter had been taught to catheterize her father, as the people were too poor to afford the services of a trained male attendant. After months of faithful work the daughter had broken down under the strain, and then the question came up as to what could be done for the patient. As a matter of course, I was opposed to performing even Bottini's operation upon this patient, but the relatives insisted upon more than palliative work, being willing to take any risk. Thus, in the summer of 1902, Bottini's operation was done at the hospital—a very troublesome after-treatment followed. The result was that the patient got rid of the catheter absolutely, and now has very little trouble with his urinary organs. In this case, truly, a great boon has been conferred upon the patient as well as his entire family by the performance of Bottini's operation. The poor old man can now at least die in peace.

*Is Bottini's Operation a Radical Procedure?*—In conclusion, a word still with regard to our right of calling Bottini's operation a radical operative procedure. We know that it is not the bulk of the gland that causes the obstruction but the high level of the internal urethral orifice, as compar d to the base of the vesical fundus. Now, if we are ab'e to overcome this obstruction by simpler means than removal of the entire gland, viz., by establ shing *permanent* gateways for the outflow of urine through the very body of the obstructing mass, such operation, I hold, must be called "radical." That this end is often accomplished has again been shown in this article Bottini's operation, to my mind, holds the same relation to prostatectomy as litholapaxy does to lithotomy in the treatment of vesical stone, or as the clamp and cautery does to Whitehead's operation in the surgical treatment of hemorrhoids. No one doubts the efficiency of these procedures in the radical cure of the troubles mentioned. Why, then, deny Bottini's operation its just and proper place in conjunction with prostatectomy in the cure of prostatic hypertrophy?

I say, the surgeon who undertakes the radical treatment of this disease *must* recognize the fact that we have *two* useful methods promising relief, methods that are not opposed to each other, but, on the contrary, complement each other.

The surgeon who practises one of the two operations only, will, of course, draw the line of indication for the particular operation further than the one who practises both and individualizes, selecting that method which he thinks promises the best result. Surely the surgeon, in order to do justice to the prostatics who entrust themselves to his care, should be able to carry out both procedures. Otherwise he will either have to condemn to catheter life such patients as are too far advanced in age or too greatly debilitated to stand the cutting operation, or, "let them down easy," as an able surgeon recently put it, in speaking of the painless death of old prostatics operated upon by means of prostatectomy.

I, for my part, do not see how we can afford to take a biased stand as regards this burning quest on.

In my opinion it is, therefore, the duty of those unwilling to do Bottini's operation, to nevertheless, advise the method in cases in which prostatectomy. seems contraindicated. It is my conviction that prostatectomy *and* galvanocaustic prostatotomy (Bottini's operation) will remain the two standard methods for the radical cure of the enlarged prostate g and.

### CONCLUSIONS.

1. The operations making a direct attack upon the enlarged prostate gland are preferable to those aiming to exert an indirect influence.

2. We have *two* useful procedures for the direct treatment of the enlarged prostate gland, *i.e.* prostatectomy and galvanocaustic prostatotomy (Bottini's operation).

3. In selecting the method indicated in the given case we must individualize and be guided by anatomic, pathologic, and socia conditions.

4. Prostatectomy is the most radical and most surgical procedure; it should be the operation of choice whenever promising success.

5. Perineal prostatectomy offers advantages over the suprapubic method, since it enables the operator to do the operation under the guidance of his eyes.

6. Debilitated patients who seem unfit subjects for the more radical operation, should not be at once relegated to catheter life, nor should prostatectomy be performed in order 'to let them down easy"; they should be advised to have Bottini's operation done if possible.

7. Surgeons should familiarize themselves with both methods, in order to be in a position to do justice to their patients.

8. It is the duty of those refusing to do Bottini's operation under any circumstances, to nevertheless, advise the latter in cases in whic the patient asks for more radical relief and the operation with the knife seems contraindicated.

9. Further carefully compiled staitstics as to the late results of both operative procedures—preferably in the hands of one man—are desirable in that they will increase our knowledge with reference to the selection of the proper method in the individual case.

### NOTES AND REFERENCES.

1. If permanent, partial retention, resulting from a semi-successful Bottini operation, would seem preferable.

2. "Remarks on the Treatment of Stone in the Bladder when Associated with Hypertrophy of the Prostate," *Annals of Surgery*, Vol. XXVII, pages 578 and 579.

3. The only exception I made was in a man with a suppurating enlarged gland; here extirpation, of course by the perineal route, was performed.

4. I found incidentally that mixing unsterilized tropacocaine crystals with sterilized water (or the outflowing cerebrospinal fluid—Guinard) is the safest way of preparing this drug for use.

5. Two deaths due to spinal anæsthesia.

6. *Centralblatt für die Krankheiten der Harn- und Sexual-Organe*, 1901, page 303.

7. *American Medicine*, 1902.

8. One of them was presented before the New York Surgical Society, April 9, 1902. Conf. *Annals of Surgery*, 1902, Vol. XXXVI, page 274.

9. This patient, reported as cured in my last article on this subject in 1900, was so classed on the strength of his own statement to that effect in a letter had I had an opportunity at the time to examine him I should have probably classed him among the improved cases rather than the cured.

10. I shall in future not subdivide results into "cured," "much improved," "improved," "not cured," but only distinguish "cured," "improved," "not cured."

11. If a patient, who considers himself cured, got rid of his catheter, urinates without pain, in a fair or good stream, 2 to 5 times during the day and not oftener than

once or twice during the night, has no vesical catarrh, or, just a trace of it, and if the residual urine does not exceed 60 c.c. = 2 ounces, I call this, with others, a cure.

12. Two cases need re-examination, having been operated upon in November and December, respectively, 1902.

## DESCRIPTION OF A PRACTICAL OFFICE OUTFIT FOR THE GENERAL SURGEON.

BY SINCLAIR TOUSEY, A.M., M.D.,
NEW YORK.

PROFESSOR OF SURGERY AND RECTAL SURGERY NEW YORK SCHOOL OF CLINICAL MEDICINE; SURGEON TO ST. BARTHOLOMEW'S CLINIC.

THE author's outfit is suitable for use wherever the ordinary electric house-lighting is installed, and, in fact, can be carried from one house to another and connected with the current by simply removing one of the incandescent lamps and screwing in a plug instead. The weight of the apparatus, however, is such that it would take an express wagon to carry it, so that, except in very unusual cases, it is only for office use. In many small towns where there is no regular electric lighting system the current may be introduced into the doctor's office from the trolley system of street cars.

The first step in the installation of this outfit is the introduction of the current into the house. The electric company tears up the street, and brings three main wires into the cellar. These (one negative and two positive) are broken by a main switch having three arms, and when this is turned off the wires and apparatus in the house are entirely devoid of electricity. In the same fire-proof box with this switch the main wires are each interrupted by a fuse. This is a short piece of lead wire through which the current has to pass, and which will not transmit a current of more than twenty-five amperes or more than two hundred and twenty volts. The fuses are permanently in position, not turned off or on by the switch, and insure the apparatus in the house against excessive currents which might burn out a hundred dollars worth of wire in an instant; but in this way just burn out this fuse, costing a few cents, and stop right there. Of course you are cut off from the current until a new fuse is put in.

The current I use is the one hundred and ten volts, direct current, but the electrical manufacturers can construct the apparatus for use in connection with the one hundred and ten volts alternating current.

From the main-switch the wires pass through a meter, which in my case is the property of the New York Edison Company, and serves as the basis for their monthly bill for current used. Then the wires are interrupted again by three enclosed fuses which burn out with a current of ten amperes and two hundred and fifty volts. Beyond this the three wires are of very heavy copper, thoroughly insulated. Where they pass through floors they are enclosed in porcelain tubes, and where they pass through long spaces in walls they are enclosed in the spiral metal tubing called "flexible conduit." Wherever passing along the surface, they are enclosed in molding, and, of course, asbestos paint is used on this.

The "wiring" terminates in the doctor's office in two different lines, each of which is controlled by a switch of the capacity of ten amperes and two hundred and twenty volts.

Beyond this switch on each line is a regular electric-light socket, into which screws a plug at the end of the flexible insulated wires leading to the different pieces of apparatus.

The first to be described is the *x*-ray outfit. This consists of a liquid interrupter, a Ruhmkorff coil, a rheostat with pole-changer and an *x*-ray tube and stand.

The positive wire passes from one of the wall sockets to the interrupter. This consists of a large porcelain jar, partly filled with dilute sulphuric acid, in which is set a smaller jar with a pinhole orifice near the bottom, also containing dilute sulphuric acid. One conducting wire terminates in a leaden ring resting in the acid in the outer jar. The current passes through the liquid and the punctured jar to a leaden plate resting in the acid in the inner jar, from which it passes by a conducting wire to the rheostat and then through the primary coil and thence back through the negative wire to the wall-socket. The principle of this particular interrupter is that when the current begins to flow, bubbles of oxygen gas are liberated from the dilute acid by electrolysis and collect at the negative electrode and bubbles of oxygen gas form at the positive electrode. These are in sufficient amount to check almost completely the passage of the current, and the instant the current ceases the bubbles of gas rise to the surface and the current flows again with full force; and again bubbles of gas interrupt it.

These interruptions take place at the rate of about eight thousand per minute, and are for the same purpose as the little vibrator in the "home medical batteries"—that is, to cause a rapid succession of currents in the same direction through the primary coil, each of which produces by induction a current of vastly greater intensity or voltage in the secondary coil. When a mechanical interrupter or "buzzer," is used for an apparatus of this power, however, a separate electric motor is required of such a size as to shake the whole floor, and the sparks which fly about are of quite a terrifying nature. The absence of noise and jarring and danger from fire are the great advantages of a liquid interrupter, and then again it is more rapid. The author's gives all the way up to twelve thousand interruptions a minute. The care required to keep such a liquid interrupter in working order is simply to pour a glass or two of water into the outer and inner jars every few weeks, while with a mechanical interrupter one may frequently have to spend an hour in adjusting the vibrator.

The next part of the apparatus is the Ruhmkorff coil, and this consists of a primary coil of copper wire wound around a soft iron armature, and surrounded by a secondary coil made up of about a hundred thousand feet, about twenty-miles of insulated copper wire. This wire is one thirty-sixth of an inch in diameter and comes already wound with silk and is coated with melted paraffin as it is wound; disks of hard rubber separate it into several sections and lessen the probability of the coil burning out when the current is turned on full. The coil is the important part of the whole apparatus, and everything depends on the perfection and permanence of the insulation. The author had three different coils made by various makers before obtaining one that was satisfactory.

The secondary coil terminates in two poles about eleven inches apart. Each of these consists of a brass base about two inches high. A hard rubber section about two and a half inches high, and a brass top with a binding post. From the two bases project steel points with insulated handles, and these can be placed at any angle. When they are horizontal they come within an inch and a half of

meeting in the middle, and when nearly vertical they transmit the current to the wires going to the *x*-ray tube, with or without a spark-gap, depending upon whether the points are in contact with the wires or not. In my own experience spark-gaps have proved essential to good *x*-ray work, and this, of course, is the object of having the posts broken by the hard rubber section instead of being continuously of metal. The sparks passing from the points to the wire are so powerful that the wire used to melt every once in a while, so I have permanently attached a short piece of heavy iron wire to each binding-post, and the conducting wires are simply hooked on to these. The sparks pass harmlessly from the points to the heavy iron wire. The connecting wires are spiral steel springs without insulation. These are infinitely more convenient than insulated copper wire, which, even if coiled into a spiral, requires the *x*-ray tube to be at just such a distance from the Ruhmkorff coil. With the springs the tube can be carried backward or forward and raised and lowered and turned about in every way without paying any attention to the wires. They take care of themselves.

The *x*-ray tube is a hollow sphere, about eighteen inches in circumference, with a cylindrical prolongation extending downward for about six inches. Through the sealed end of this passes the cathode, terminating in a concave mirror of aluminum just where the cylindrical part joins the spherical part of the tube. Above, there are two cylindrical projections, through one of which passes one anode, called the anticathode, terminating in a disk of aluminum just where the cylinder joins the sphere. The anticathode and the cathode are, so to speak, at opposite ends of the tube. The other anode enters the tube obliquely through a cylinder and terminates at the center of the spherical part of the tube in a disk or mirror of platinum. This mirror is at the exact focus of the concave mirror forming the cathode. The whole tube is hermetically sealed and contains a partial vacuum.

When in use, a direct current of very high voltage and very rapidly interrupted is driven from the cathode to the anodes through this partial vacuum, and the molecules of gas are projected from the concave cathodal mirror to the plane platinum anodal mirror, from which they are diffused in such a way that the whole hemisphere in front of the mirror is filled with a greenish light. This light is not the *x*-ray, but is present with it, and to the experienced eye is a perfect guide to the quality and intensity of the *x*-ray. The latter, of course, is invisible to the naked eye. If the hand be held up before the *x*-ray tube in operation, no special effect is noted. If you were in a dark room and the *x*-ray tube in operation were encased in cardboard, no light would be visible. But the invisible *x*-ray would penetrate the cardboard and would cause a bright green fluorescence in any surface coated with certain chemical substances, most commonly barium compounds. In such a darkened room you could hold your hand toward the place where the *x*-ray tube is known to be concealed, and hold a piece of cardboard, coated with such a chemical between your hand and your eyes, with the prepared surface toward you, and then you would notice a bright green fluorescence in the cardboard, shaded more or less by the rays having to pass through the bones and soft parts of the hand. It seems exactly as if you were looking at the bones and flesh through a more or less transparent medium, but what you really see is a shadow upon the fluorescent surface. A piece of cardboard prepared in such a way is called a fluoroscope, and if it is turned with the chemical surface away from the observer you see nothing at all. The idea is that the invisible *x*-rays will pass through almost any substance and excite fluorescence in certain chemicals. This fluorescence is ordinary light, and to see it you must have it exposed directly to view. For every-day use the fluoroscope forms the bottom of a dark box which can be applied to the eyes in such a way as to exclude all ordinary light. The chemical surface is toward the eyes, and when the apparatus is held up toward the *x*-ray tube the bottom is so brightly fluorescent as to seem transparent. Especially is this the case when some object like the hand is held between the *x*-ray tube and the fluoroscope.

The bones and all are so clearly seen that several times people have expressed surprise when they discovered later that they were not looking through a piece of glass, but through a heavy sheet of black cardboard. Using this apparatus, the room does not have to be darkened, though I think that slightly better results are obtained if it is dark. The *x*-ray appears to be interfered with to some extent by the presence of ordinary light waves, This fluoroscope is easily held in one hand, and with it we can at once see the condition of the bones and joints in any of the limbs, the condition of the ribs, clavicle, scapula, vertebræ, lungs, heart, liver and spleen. The fluoroscope hardly gives us a useful view of the pelvis or the hip-joint. The spleen and liver can be seen clearly enough, and abnormal size or lessened mobility during respiration are easy to demonstrate. The size, shape, and position of the heart are seen, and the density of the lungs is noted.

The *x*-ray tube is held in any required position by a stand consisting of a heavy iron base, with an iron upright, from which extends a wooden arm. The tube itself is provided with a separate prolongation by means of which the degree of vacuum is regulated. A tube which is "hard," *i. e.* in which the vacuum is very high and the gaseous contents are almost completely exhausted, as by overheating, shows greenish spots over the unlighted hemisphere, and the line between this hemisphere and the bright one is not sharply defined. A "hard" tube produces a light of great penetrating power, and is desirable for fluoroscopic examination through great thickness of tissue; but is not so desirable for fluoroscopic examination or photography of the bones of the hand or forearm. These bones look transparent and do not present the beautiful contrast which they do when examined with a "soft" tube.

Like every other scientific means of observation, a great deal more is seen by the practised eye than by one unaccustomed to this work, and especially is this the case here because a long study of the image is prohibited by the danger of an *x*-ray burn. Right here comes in the value of an *x*-ray photograph, which shows everything that can be seen with the fluoroscope and which can be studied and demonstrated as carefully and for as long a time as necessary.

The author is about to publish a description of a new process by which an *x*-ray photograph may be made and handed about the room in five minutes and fifteen seconds after the patient comes into his office.

Quite another portion of the outfit is a set of vacuum-electrodes for the high-tension discharge. Each of these is a vacuum-tube of a size and shape corresponding to the part to which it is to be applied. One has a flattened, bulbous extremity, and is applied to the surface of the body; and others are of special shapes for introduction into the bladder,

rectum, vagina, nose, and ear. Such a tube is held by an insulated handle, and is connected with one pole of the Ruhmkorff coil, the rheostat being turned quite low. There is no connection with the other pole of the coil.

When the current is turned on, this tube becomes filled with waves of faint light, which apparently enter the body where the tube touches it. If the tube is held at a little distance from the body a shower of sparks passes from the tube to the body, and this is more or less disagreeable, according to the sensitiveness of the skin. This portion of the outfit is purely for therapeutic purposes, and the author has obtained extraordinary results in infantile paralysis, rheumatism, sciatica, lumbago, and especially in chronic colitis and impotence. For most purposes it is better to have the tube in contact with the surface, and then scarcely any sensation is perceptible and absolutely no disagreeable effects.

The portion of the outfit used for the production of the Finsen or ultraviolet ray consists of a Görl lamp as modified by Dr. Piffard, and described by him in a recent article, and a medium-sized Leyden jar. The whole being connected with the *x*-ray coil. The outer surface of the Leyden-jar is connected with one pole of the coil, and the inner surface with the other pole, no spark-gaps being used at either connection. The Leyden-jar acts as a condenser, and is absolutely necessary to the production of the ultraviolet ray. To the two poles of the coil are also attached the insulated wires leading to the Görl lamp. This connection with the coil is also without spark-gaps. The Görl lamp itself is easily handled, and consists of a hard rubber cylinder, at one end of which enter the insulated wires from the coil. These terminate in two brass knobs at the other end, between which are two others; the whole producing three spark-gaps. This end of the lamp is covered in by a lens of quartz-crystal which is transparent to the ultraviolet ray. When in use these sparks give out a noise like a package of firecrackers and the light has a faint, violet color.

The presence of the ultraviolet ray in the light from this lamp is demonstrated by the beautiful green fluorescence produced in a piece of willemite, an ordinary looking rock, consisting of silicate of zinc. This fluorescence is prevented by the interposition of a piece of glass or of a piece of the thinnest tissue paper. And this is in very marked contrast to the *x*-ray, which will penetrate the thickest book. The ultraviolet ray is present in very small amount in sunlight, and its presence may be demonstrated beyond the violet end of the spectrum. Of course it is invisible. Originally it was obtained for curative purposes from sunlight by means of lenses concentrating all the rays and a layer of water or rock-salt to absorb the heat rays. Its production from electricity in various ways marks a very great advance.

Therapeutically the ultraviolet ray is limited to action upon the external surface of the body, and if it is to penetrate even the thickness of the skin, as in lupus, we must press the blood, which is opaque to these rays, out of the part, and this is one reason for having the quartz crystal covering the end of the lamp. This can be pressed firmly against the surface. Or, again, the part may be blanched by the application of adrenalin chloride. This will be absorbed all right by a raw surface or a mucous surface, but to blanch the unbroken skin we have to follow Dr. Piffard's suggestion and introduce the adrenalin chloride by electrolysis. The conditions which are benefited by it are especially lupus, and acne, eczema, epithelioma, and chronic ulceration.

One of the standard tables giving a variety of positions gynecological and otherwise, is a necessity for treatment by the *x*-ray and by the vacuum electrodes. Therapeutically the *x*-ray proper is invaluable in inoperable malignant disease and in acne, lupus, psoriasis, nævus, and colitis.

The final portion to be described is a portable switch-board connecting with the electric light service and containing rheostats and converters of various kinds, and a milliamperemeter. This gives all the varieties of galvanic and faradic electricity required for ordinary therapeusis and for electrolysis and for diagnostic illumination. This is contained in a box measuring about eight by eight by thirteen inches, and is connected with the wall socket by means of a flexible cord and plug. The various accessories, such as the urethroscope, sponge-electrodes and electrolytic needles require no description. This part of the apparatus can be taken to any house where there is electric light.

The cost of electric current for such an outfit is very small. Not more than five or ten cents an hour for *x*-ray and vacuum-tube work, and next to nothing for galvanic and faradic work. The apparatus is always in working order day and night, dry or damp weather, and has great advantages over a static machine in therapeutic uses.

## THE CHOICE OF METHOD FOR THE RELIEF OF RETROVERSION AND RETROFLEXION*

By JOHN VAN DOREN YOUNG, M.D.,
NEW YORK.

A multiplicity of methods in use for the relief of any condition of deformity or disease of the human body usually means that none of them is satisfactory, or that the principles governing the employment of the various useful procedures have not been understood clearly, and have given rise to a feeling of dissatisfaction on the part of the operator, and an effort to devise a new operation has been the result.

It is my feeling that the latter has been the case in dealing with retroversion, and retroflexion of the uterus. Each individual operator has employed some method, found it lacking, and becoming imbued with a belief in the great benefit of some other procedure, has gone to the extreme of thinking that because there was a retroversion or retroflexion, this method would relieve it, instead of recognizing that the condition was a complex one, and involved many structures, and any method of procedure must be in accord with the condition he sought to relieve.

My desire is to point out the factors that should govern us in choosing one of the recognized methods of treatment; and my deductions are founded on eleven years of clinical experience, during which I have had the opportunity to observe the results of treatment as applied by many gynecologists and general surgeons, long after they have lost sight of the cases, and on my own operative and non-operative cases and the literature on the subject.

I am free to say that my clinical experience has led me to be much more conservative as to the ultimate results in the relief of symptoms than one would think necessary when reading papers on new operations.

I shall not burden you with the report of many cases, or quotations at large, from a very voluminous literature, but will first ask your attention to the conditions found in a normal female pelvis:

*Read before the New York Obstetrical Society.

*Uterosacral Ligaments.*—The uterus is a solid scular organ suspended in the true pelvis by the rosacral ligaments from the under surface of the nd sacral vertebra. These ligaments are very ng fibrous bands, especially well marked in the ng child, and are the only ligaments of the uterus ffected by pregnancy or delivery. They are the st important ligaments that suspend the uterus n the patient stands, walks or sits; they, how- , sink into insignificance when a dorsal examina- is made, or when the abdomen is opened. At psy I have tried to rupture them, and their gth has always been a matter of surprise. In examination in the dorsal position they may be y demonstrated by lifting the cervix upward by index-finger, placing the middle finger between cervix and the rectum and moving it slightly side to side.

cond in importance, as suspensory ligaments, the *Broad Ligaments*. These hold the uterus rally, and between their folds of peritoneum e many strong fibrous bands that extend from terus to the side of the pelvis, and add greatly e support of the uterine body. These ligaments ffected secondarily by pregnancy, although the s bands may not be injured enough to inter- with their functional usefulness.

e *Round Ligaments*, as their name indicates, two cord-like musculo-elastic guy-ropes that the fundus antero-laterally, but have no in- ce on the lower segment of the uterus, and not suspensory in their action in the least e. These ligaments are most markedly affected regnancy, greatly increased in length, and un- perfectly involuted are lax after one pregnancy. as always impressed me that at autopsy or at ation, the body being in the dorsal position, the round ligaments are always lax, and can be ched to a very considerable degree with the test ease.

ven when the fundus is in normal position, and pathological condition affecting them is present, impossible for me to imagine them tense enough n themselves shorten the distance from the fun- to the symphysis. In considering these liga- nts it must also be remembered that they leave uterus in the anterior folds of the broad liga- t, and pass in a lateral, downward, slightly erior direction to the internal inguinal ring, and traction on them tends to lower, as well as pull ard, the fundus of the uterus. The direction is illustrated by the large claws of a crab.

he normal fundus can be retroflexed or the uterus verted with the greatest ease at bimanual mination, the round ligaments offering no re- ence; but if the uterosacral ligaments are normal exceedingly difficult to stretch them so as to w an equal displacement of the lower uterine ment.

The levatores ani and pelvic fascia form the pelvic phragm, upon which the intraabdominal pressure inges. The rectovaginal septum is the anterior port of the rectum and prevents rectocele. ither of these structures support the uterus di- tly, but injuries to either or both seriously in- ease the strain on the uterine ligaments.

*Condition Found When There Are Retroflexion, troversion, or Both.*—First, the distance from the der surface of the second sacral vertebra, to the rporo-cervical junction of the uterus, is always creased. Upon the amount of increase in weight d bogginess of the uterus will depend the amount flexion, the existing version being governed by the mount of stretching of the utero-sacral ligaments. I am convinced that these ligaments may in great measure regain their tone and suspending power when the malposition has been relieved and the normal pelvic circulation returns.

The broad ligaments are more or less lax

The round ligaments are lax, and stretched.

The *pelvic fascia* may with the *levatores ani* be unaffected, allowing little or no prolapse of the pelvic diaphragm.

The *uterus* is chronically congested; an adenomatous hyperplasia of the endometrium always exists.

*Classification.*—For convenience in description, it is well to consider the following variations of this form of malposition of the uterus: (1) acute, traumatic; (2) subacute, not complicated by adhesions; (3) chronic, with or without adhesions.

All these may, or may not, be complicated by other lesions of the adnexa, injuries of the cervix, and rectovaginal septum.

CAUSES.—In *nulliparæ:* Chronic uterine congestion. Increased intraabdominal tension. Chronic constipation, with straining at stool. Lack of care of bladder. Over-exertion, especially at the menstrual period. Falls.

In *multiparæ:* All the causes operative in nulliparæ, together with injury to the cervix, as a factor in causing chronic uterine congestion. Injuries to the rectovaginal septum. These injuries are of great importance for the following reasons: The rectovaginal septum acts as an inclined plane, on which the fecal content of the bowel impinges; the anus is held in its normal position by the four superficial muscles of the perineum; now, given a destruction of the normal resistence of the rectovaginal septum, and an anal retraction, both occurring from the same cause, namely, injuries to the muscles, rectocele is the inevitable result. There must be from these conditions an overloading of the rectum with fecal matter for a part of the twenty-four hours anyway; and there is loss of the normal act of defecation, and a necessary great increase in straining at stool; these patients have many times told me they were compelled to lift up the rectocele with the hand before defecation was possible.

One other factor must not be forgotten, namely, injury to, or yielding of, the pelvic fascia and levatores ani; when these are present the dragging on the uterosacral ligaments is greatly increased, and it is liable to produce a prolapse.

It seems logical that the rectal tube passing as it does between these ligaments and intimately attached to the lower segment of the uterus, and to them, would, when the normal mechanism of defecation was lost and when greatly overloaded, and when straining is brought to bear to empty it, greatly increase the suspensory load of these ligaments, and tend to stretch and weaken them.

One other point worth considering is the frequency of *adhesion* of the retroflexed or verted uterus to the walls of the pelvis; this prevents to a great extent prolapse of the uterus, and while complicating the operation has probably saved to the patient structures that would otherwise have been rendered useless.

CASE.—These facts were never more graphically impressed upon my mind than in a case I saw at my clinic at St. Luke's Hospital. The patient had been operated upon by a most skilful gynecologist some time prior to her visit, ventral fixation having been performed. The patient came complaining of a large rectocele. I found the cervix outside the vaginal introitus, the cervix large and lacerated, the uterus large, a large rectocele, with marked anal retraction. To my surprise the fundus was firmly adherent to the anterior abdominal wall, the cervix had traveled through an arc of a circle, until the

uterus occupied the anterior third of the pelvis. The fixation of the fundus was absolute, but the uterosacral ligaments were incapable of bearing the enormous increase in the burden and had yielded, the pelvic fascia and levatores ani having been damaged so as to afford no help.

From the foregoing it is logical to draw the following conclusion: Any method applied for the relief of retroversion and retroflexion must consider all the structures involved in the deformity of a given case, the degree of their involvement, and the possibility of regaining normal tone and supportive power after relief of the unnatural strain.

The non-operative and operative methods applied to these conditions are as follows: *Non-operative* measures are applicable to acute traumatic, and to uncomplicated, non-adherent cases. In traumatic cases, rest in bed, ice-bag to the abdomen, and hot douches, with local treatment, as for non-adherent cases.

In cases of non-adherent replaceable malpositions, care of the patient's general health is necessary, with prolonged rest in bed when possible. Local treatment, as tamponade, douches, pelvic massage, electricity, and the pessary is called for. The knee-chest position in treatment, douching, and replacement and in the introduction of a pessary, is a valuable adjunct. Curettage will often aid, and any lacerations should be repaired. If adhesions are diagnosed, or there exists disease of the adnexa, some form of laparotomy must be resorted to, either through the vaginal vault, or suprapubic.

The operative procedures directed to the relief of retroflexion and version are as follows: Alexander's operation; shortening the round ligaments intra-abdominally, either through the vaginal vault, or by suprapubic incision; cutting the round ligaments at their origin and forming a sling for the uterus by passing them through the broad ligaments and suturing them posteriorly; anchoring the round ligaments into the anterior abdominal wall. Vaginofixation; ventral fixation; ventral suspension; sacrosuspension; Bissell's operation.

*Alexander's Operation.*—I well remember a case in which an advocate of this operation performed it with the greatest ease, and had apparently a perfect result; no repair of a badly lacerated cervix and perineum was done; later the patient's symptoms returned and she applied for relief. An anterior vaginal section was performed and adhesions were found so dense that a posterior incision was required to sever these, and then an intraabdominal shortening of the round ligaments was done, on ligaments already shortened by the Alexander operation. A complete repair operation was then performed. I mention this case as an illustration that even in the hands of skilled operators work of this kind may be unsatisfactory.

The round ligaments from their direction are guy-ropes only, not suspensory ligaments, and I am convinced that it is a fallacy to expect traction on them to hold the fundus forward when there is retroversion and prolapse. I believe the field of usefulness of this operation is limited to cases of retroflexion, and does not apply to retroversion, or when they co-exist, unless the uterosacral ligaments are strong and the pelvic diaphragm, intact.

It is interesting to note that Dr. Howard Kelly does not describe this operation in his "Operative Gynecology."

*Intraabdominal Shortening of the Round Ligaments.*—Intraabdominal shortening of the round ligaments by any of the various methods suggested, by either vaginal or suprapubic route, possess slight advantages over the Alexander, as they differ only in mode of procedure.

The round ligament—uterine sling I simply mention.

*Vaginofixation.*—Vaginofixation has been advocated by some operators.

All these methods presuppose that the fault lies entirely with the fundus, and when this is the case will give results; but when retroflexion is only part of the trouble relief will not be obtained.

I am convinced that the reason the vaginal route in these operations has given the best results is because all complicating lesions are dealt with; while operations in the dorsal position seem to lessen their importance, and make the operator satisfied with the round ligament shortening alone.

*Ventral Fixation.*—This operation is applicable only to patients who have passed the child-bearing period of their lives; should pregnancy occur the dangers of uterine dystocia are very great.

It must also be borne in mind that the fundus is not normally fixed, as the respiratory motion, and movement to allow the bladder and rectal distension are interfered with, and the uterus is held higher up than normally.

There is also a peak-like lifting of the floor of the pelvis which in old relaxed conditions does little harm. This malposition will, if careful repair of all lacerations is done, be much more acceptable to the patient than the misery from which she sought relief; still, it is a malposition and should only be done when ventral suspension with sacral suspension, together with repair, do not promise to be enough to prevent prolapse. I venture to prophesy that fewer of the operations will be done in ten years than are done now.

*Ventrosuspension.*—As its name indicates, it is a suspension from the anterior abdominal wall by bands of peritoneal exudate; these should be made by suturing the uterine fundus to the anterior abdominal wall with No. 2 chromic acid catgut. There are two stitches passed as follows: Entering the anterior surface of the fundus three-quarters of an inch below the upper border, and half an inch from the median line, on either side, they are made to pass from the uterine peritoneum half an inch below and slightly to the outside of the point of entrance. The needle is then made to pass through the ventral peritoneum on the outer side of the incision about one inch above the symphysis. The stitches are exactly alike on both sides.

This method gives excellent results and the possibility of uterine dystocia in subsequent pregnancies is very remote. The fundus is allowed ample play, and the possibility of a return to the malposition slight.

The possibility of interstitial strangulation, or intraabdominal hernia, between or under these bands, I believe, is nil, for the relation of uterus, bladder, and symphysis would seem to render it impossible.

In the application of both of these methods the uterosacral ligaments must be carefully examined, and if overstretched they must be shortened by one of these methods, three in number, as follows: (1) Splitting in a longitudinal direction, separating the edges by traction on the center of each lip of the wound, thereby transforming a longitudinal to a transverse cut and suturing the wound. (2) Section of ligament at its middle and over-lapping and suturing. (3) Shortening by puckering stitch and relying on the peritoneal exudate to re-inforce the ligament. Chromic acid catgut should be used.

I cannot lay too much stress upon the necessity

n these operations of repair of vaginal tract injuries, ombined with curettage, and repair of cervix.

*Bissell Operation.*—The operation devised by Dr. Dougal Bissell of this society, combined with shortning of the uterosacral ligaments when needed, lso repair of lacerations, presents the most perfect rocedure now known in theory, and I am sure the heory is correct, and will be borne out in practice. He shortens the round and broad ligaments by esecting one inch or more of the round ligament; y traction on the center of either lip of the resulting ound the cut is transformed from a longitudinal ne to a transverse, thereby shortening and thickning the broad ligaments. Interrupted catgut utures are used in closing the wound. Particular are is used in approximating the cut ends of the ound ligaments. This procedure is repeated on the pposite side. The operation is difficult in stout eople and requires some time to perform.

*Deductions.*—1. Retroversion and retroflexion are ever simply malpositions of the fundus, but omplex changes in the relation of the whole terus to the other structures in the pelvis and to he pelvic wall.

2. The uterosacral ligaments are the only suspenory ligaments of the uterus when the patient stands, nd are the only ligaments not affected by gestation r parturition.

3. The uterosacral ligaments suspend the uterus y their attachment to the lower segment and act as swing in supporting the rectum. Factors causing he yielding of these ligaments are: Injuries to pelvic iaphragm; increased intraabdominal pressure; onstipation; straining at stool; injuries to the ectovaginal septum, causing retraction of anus, ith rectocele.

4. Any method for the relief of these conditions nust consider and relieve all the complicating leions, not the least of these the pathological condiion of the endometrium.

5. All methods for holding the fundus forward must rely upon the integrity of the uterosacral ligaments, together with the fibrous connective tissue of the broad ligaments to suspend the uterus.

6. Non-operative measures are applicable to acute traumatic and replaceable non-complicated cases and depend for their value upon relief of pelvic engorgement, the restoration of normal circulation and the return of normal elasticity and tone to the ligaments and muscular structures.

7. The Alexander operation has a limited field of usefulness, and is of value only when there is retroflexion and the other ligaments are strong enough to support the uterus, with proper relief of other complications. It must never be forgotten that traction on the round ligaments tends to lower the plane of the uterus.

8. Ventral suspension, when performed in combination with other procedures, does relieve the malposition, and prevents a recurrence of the same. Its dangers, when properly performed, are small if any in subsequent pregnancies. The advantages of the operation are the ease and rapidity of its performance.

9. Ventral fixation is applicable only when the patient has passed the child-bearing period.

10. The ideal procedure is as follows: Curettage; repair of injuries to the cervix, retrovaginal septum, and anterior wall of the vagina. Laparotomy. Sacrosuspension. Bissell operation. The disadvantages are the length of time necessary for the operation and its difficulty of performance in fat subjects.

11. In place of the Bissell operation, a ventral suspension may be substituted. This, I believe, is wise when many adhesions have been broken up and the posterior surface of the uterus is denuded of peritoneal covering, or the patient's condition demands haste.

12. In nulliparæ a pessary should be worn for six months to prevent traction on the uterosacral ligaments until they have regained their tone. The action of the pessary is due to the fact that resting on the superior surface of the symphysis the lower segment of the uterus is held upward, and the strain taken off the uterosacral ligaments. The rectocele, when no lacerations exist, is in this manner lessened.

13. The uterus should be curetted as the first step in any of these operations.

14. The adhesions so frequently found in these cases are of the greatest value to the patient in that they fulfil a munificent purpose of nature in preventing the condition of complete prolapse during the existence of the malposition.

60 West Seventy-sixth Street.

## THE NON-MEDICINAL TREATMENT OF CONSTIPATION.*

By SAMUEL G. GANT, M.D., LL.D.,
NEW YORK.
PROFESSOR OF DISEASES OF THE RECTUM AND ANUS, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

INNUMERABLE remedies have been suggested for the relief of chronic constipation, but the successful treatment of this common and most persistent and annoying affection still remains a difficult problem. Frequently the failure to obtain good results is due to injudiciously prescribing purgatives, carthartics, and enemata when the costiveness is caused by fissure, polypi, hemorrhoids, hypertrophy of the rectal valves, congenital malformations, benign or malignant stricture, or other disease of the rectum, sigmoid or colon, requiring operation or local treatment. Again, a very large percentage of cases of constipation are the result of irregular habits, improper diet, lack of tonicity, and glandular secretion of the bowel, or insufficient exercise, and must be treated by correcting these conditions; it is in this class of cases that the physician, in his desire to obtain "quick action" is inclined to overdrug the patient and disregard entirely more rational methods which may be less satisfactory in the beginning, but which eventually effect a permanent cure.

The writer has not resorted to the use of drugs for the relief of constipation for many years, and in January, 1891, before the Kansas City Academy of Medicine, he reported a number of cases successfully treated by the *non-medicinal method.* Since that time he has treated several hundred cases by this method, and the majority were permanently cured, while the remainder, with but few exceptions, were relieved to a greater or less degree.

The principal features of the non-medicinal method as practised by the writer are the proper education of the patient, together with the administration of enemata when necessary, massage, the application of electricity, divulsion or division of the sphincter muscle, and valvotomy, any one or all of these simple procedures being carried out as the case demands. Success in handling these cases depends entirely upon persistently and carefully applying the above measures for as long a time as may be required, and patients should be informed that the stools may not be regular or copious in the

*Read before the Medical Association of the Greater City of New York.

beginning, but that it may be several weeks before the desired results are obtained.

*The proper education of the patient* is very important, and the attendant must insist that his instructions be carefully followed. Temperance in manner of living and regularity of habits are essential. In order to procure proper digestion and assimilation and normal evacuations, persons suffering from costiveness should take their meals at regular hours, and under pleasant surroundings, eat slowly and moderately, and abstain from foods which disagree with them, or which tend to clog the intestine. Such fruits as apples, oranges, bananas, figs, and prunes, which are known to have a laxative effect, should be included in the dietary and should be eaten preferably in the morning or just before retiring.

In order to soften the fæces and stimulate peristalsis, it is necessary to drink freely of water throughout the day, there being but few more reliable laxatives than two or three glasses of cold or warm water taken on the empty stomach in the morning. Since an inactive life is conducive to constipation, these sufferers, especially if engaged in sedentary occupations, should take plenty of systematic indoor or open-air exercise. Frequently chronic constipation is complicated by a severe type of autointoxication, and in these cases a cold bath each morning, followed by a salt rub, or vigorous friction of the skin with a Turkish towel, acts as a tonic, stimulates circulation, and opens up the pores, thus assisting nature to eliminate the poisons.

It is an accepted fact that by persons regular in habit the desire to go to stool is experienced at about the same time each day, while by others, negligent in attending to the calls of nature, this desire may be felt but once in several days. Therefore, patients suffering from constipation should be instructed to make an effort to empty the bowel at a given hour daily, to devote sufficient time to this effort, and not to make the toilet a reading room. They must not be discouraged if the evacuations are irregular and incomplete at first, as the results sought for will be accomplished if the treatment is perseveringly carried out.

The administration of *enemata* daily to evacuate the bowel is a most pernicious practice, and the custom of some physicians to advise their habitual use is to be condemned. Early in the non-medicinal treatment of some cases, however, in order to secure necessary evacuations and prevent fecal impaction rectal and colonic injections are justifiable, but their use must be discontinued as soon as the other measures suggested have become effective.

*Massage* intelligently practised is an essential feature of this method of treatment, and for a number of years the writer has successfully employed it, alone, or in conjunction with other measures in the treatment of habitual constipation. It is valuable because it improves circulation, loosens adhesions, dislodges and breaks up fecal impaction, restores tone to fatigued and inactive muscular fibers, excites the liver and intestinal glands to renewed activity, and assists in establishing normal peristalsis. In addition to kneading of the large intestine, special massage should be given over the liver and small intestine and locally to the rectum by means of the hands or vibrator.

For *abdominal massage* the patient is placed in the recumbent posture upon a table so arranged that the head may be raised or lowered and the body rotated from side to side, thus changing the intestines from one position to another. The masseur then makes firm but gentle pressure with the palm of the hand and ball of the thumb over the large intestine, beginning in the right and following the course of the colon into the left iliac fossa and accompanying the pressure by thorough kneading of the parts with the fingers. This should be repeated several times during ten or twelve minutes, and every other day at first, while later in the treatment twice a week will suffice. The patient himself should not attempt these movements, as deep manipulations are prevented by the contraction of the abdominal muscles which follow his efforts; if unable to pay for the massage, he may receive much benefit from daily rolling a cloth-covered metal or bowling ball over the course of the colon while lying in a recumbent position.

*Electricity*, in the form of both the faradic and galvanic currents, has been highly spoken of as a treatment for constipation in most of the works devoted to electrotherapeutics. The writer is not prepared to say that its application alone is efficacious, but, in combination with the other measures suggested, he has found it valuable in many cases. It would appear that electricity exerts a beneficent influence in that it restores tone to the abdominal and intestinal musculature, stimulates the nerve centers, increases peristalsis, and excites glandular secretion. The positive electrode may be placed over the spine, or introduced into the rectum or sigmoid colon, while the negative is moved about the abdomen over the region of the liver, the small intestines, and colon. The intestinal contractions can be easily observed and felt through the abdominal wall. The frequency of the application depends upon the case, and its duration should be from five to ten minutes.

*Divulsion of the sphincter muscle* is very often necessary in cases of chronic constipation in either adults or children when the muscle has become hypertrophied or irritable and offers an obstruction to the evacuation of the fæces. Many of the writer's patients in whom the muscle has been divulsed or divided during operation for other rectal affections have remarked sometime afterward that their constipation also has been cured. From his observation of these and other cases where the sphincter was stretched for the relief of chronic costiveness, he is convinced that hypertrophy of the muscle is an important factor in the etiology of constipation, and that its divulsion or division is frequently indicated.

*Gradual divulsion* may be accomplished in the office by means of the Kelly or Pratt Anal Dilator, the Wale's graduated rubber bougies, or the introduction of one, two, and then three fingers until the anus has become sufficiently relaxed.

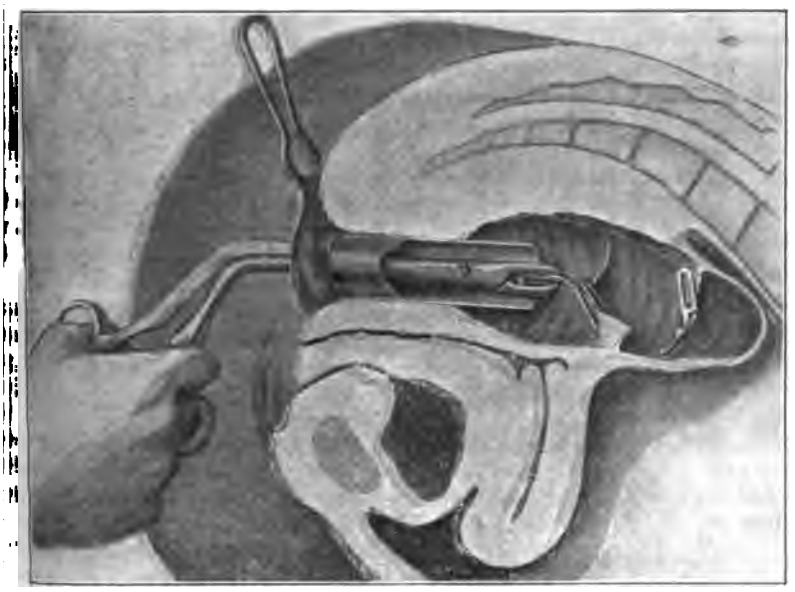
*Forcible or rapid divulsion* requires general anæsthesia, and is performed by stretching the muscle in every direction with the thumbs until its resistance has been overcome. The advantage of using the thumbs for this purpose rather than mechanical dilators or large specula is that tension of the fibers is easily recognized, and the direction of the pressure can be changed, thus avoiding rupture of the muscle and subsequent incontinence.

In some cases the sphincter is so thick and strong that the necessary amount of relaxation cannot be obtained by divulsion, however thoroughly done, and *complete division* is required. This can be performed by injecting 3 per cent. beta-eucaine into the section of the sphincter to be incised, introducing a bistoury guided by the finger placed above the muscle and then withdrawing it, completely dividing all the fibers laterally or in the posterior median line; the after-treatment of

wound is the same as that following cutting operations for fistula.

*Valvotomy* is occasionally indicated when one or more of Houston's valves have become so hypertrophied as to obstruct the descent of the fæces. Martin was the first to suggest division of the thickened valves for the relief of constipation. He exposes, through the proctoscope, a section of the valve in which two tenacula are now fixed, and between these the fold is incised with a specially devised knife. The cut edges of the mucous membrane are then approximated and held by catgut sutures, secured with perforated shot; to make the cut, to introduce the sutures, and to adjust the shot requires a knife, needle, and shot carrier having long handles bent at an angle so as not to obstruct the view. The operation is completed by tamponning the rectum with non-absorbent cotton dusted over with iron sulphate to arrest bleeding and prevent infection. The patient is then placed in bed with feet elevated and ice-bags applied to the lower spine.

The objectionable features of the Martin operation are its difficulty, the number of instruments and time required, the danger of hemorrhage, infection and peritonitis, the great pain and distention due to the tampon, the confinement of the patient in bed for a week or more, and finally the fact that no part of the obstructing valve is removed. To meet these dangers and difficulties, Pennington suggested a clip for the purpose of dividing the valves by pressure-necrosis. With this idea in mind, the writer has devised and perfected his fenestrated valve-clamps and forceps applicator, which render the operation extremely simple and devoid of danger.



Gant's operation of "Valvotomy," showing manner of using his new forceps-applicator and "valve" clamps. One clamp is in position and another placed over a "valve" ready to be freed from the applicator.

The *technique* of the *clamp* or Gant operation, is as follows: The rectum having been cleansed, the patient is placed in a knee-chest posture and a proctoscope of suitable length and caliber is introduced and so adjusted that the border of the valve crosses the center of its aperture. The applicator carrying the open clamp is then introduced, the clamp is slipped well down over the valve and released, after which the forceps and proctoscope are removed (see cut). When properly constructed the clamp divides the valve in from four to six days, depending upon the amount of fibrous tissue present, and is discharged with the fæces carrying the section of tissue within its grasp. Some of the advantages of the clamp operation are that it is simple and can be painlessly performed in the office in from one to five minutes, there is no danger of hemorrhage, infection or complications, no dressings are required, and the patient is not detained from his usual duties, suffers but little, if any, discomfort, need not be restricted as to diet, and takes nothing to regulate the frequency or consistency of the stools.

In the writer's experience this operation has proven more effective than the cutting procedure, because it removes a section of tissue nearly half an inch wide and about an inch long, thus insuring wide separation of the remaining segments of the valve.

Valvotomy is unquestionably indicated at times, but not in as great a proportion of cases as its most enthusiastic advocates would lead us to believe. The writer would suggest that the frequency of the stools following valvotomy cannot be attributed solely to the increase in the lumen of the bowel, because at the time of operation the sphincter muscle must be divulsed by the introduction of the large proctoscope and, moreover, the irritation produced by the incision or the presence of the clamp and the subsequent ulceration and proctitis excite increased peristalsis similar to that so often observed in ulcerative or inflammatory diseases of the lower intestine. In cases of long duration, after the rectal valves have been divided, it is sometimes necessary properly to educate the patient and carry out other measures already suggested in order to overcome the habitual constipation.

In conclusion, the writer would state that in his experience the results obtained from the *non-medicinal method of treating* chronic constipation are by far more satisfactory and permanent than those following the use of drugs.

43 West Fifty-second Street.

**British Losses in the South-African War.**—There were lost in men, killed outright on the field in battle, or in those who succumbed to wounds and sickness, 21,942, and 75,430 more were invalided home as sick or wounded.—*Review of Reviews.*

**A Case of Popliteal Aneurysm in a Young Boy.**—I. F. Black records the case of a boy of nine years with a good family history, and a personal history of measles and diphtheria. When the author was called to see him he had difficulty in breathing, loss of appetite, and insomnia. The organs all appeared healthy, except the heart, in which various murmurs were heard; but the principal lesion of which was incompetency of the aortic valves. A month later he developed stiffness and pain in the left knee, and a few weeks after this an aneurysm was found in the popliteal space. Operation was decided on, and the sac removed with some difficulty, because of the thinness of its walls, and the intimate adhesion to the surrounding structures. In spite of the grave condition of the heart, and the weak condition of the boy, he took chloroform without the slightest difficulty and was under the anæsthetic for an hour. The aneurysm arose from the posterior wall of the popliteal artery, just behind the posterior ligament of the joint, and was the size of a large walnut. The boy made a good recovery from the operation and regained perfect use of the limb. —*Pediatrics.*

## THE FREQUENCY WAVE OF EPILEPTIC SEIZURES.

By WILLIAM P. SPRATLING, M.D.,
MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS. SONYEA, N. Y.

WHILE there is a great variation in the frequency of epileptic attacks, as shown in part by the few cases cited below, reference to the greater number studied—1,374—indicates that under certain conditions a crude periodicity seems to characterize the time of expression of the majority of them:

Case No. 275: attacks occurred at first 10 to 15 a day: later they increased to 30 to 70 daily.

Case No. 399: attacks occur at present every few days. Patient has had intervals of nearly a year between paroxysms.

Case No. 630: attacks at first from 4 to 6 weeks apart; at present they occur once a week.

Case No. 650: patient has had only 5 or 6 attacks during a period of several years.

Case No. 685: attacks occurred at first at the rate of one a year—all petit mal.

Case No. 714: has had one attack only every spring for the past three years, all of them at night.

Case No. 829: the patient at first had 6 or 8 psychic attacks—"stares" he called them—a day; now he has 3 or 4 grand mal seizures in the same length of time.

Case No. 907: attacks at first occurred every half hour; now once in about four weeks.

Case No. 1003: petit mal attacks daily; grand mal attacks once a year.

Case No. 1045: grand mal attacks occur from one a week to three months apart; petit mal attacks at the rate of 20 to 40 a day.

Case No. 1052: attacks first occurred once in two weeks; mostly petit mal; has a grand mal attack once a year.

Case No. 1113: attacks at first occurred once a month; later, 2 to 7 in 24 hours.

Case No. 1177: attacks at first occurred on an average of 15 months apart; now they occur weekly.

In 1,374 cases at the Craig Colony the approximate frequency of the attacks was as follows: Attacks weekly or oftener in 775; every two weeks (about) in 173; every three weeks (about) in 61: every four weeks (about) in 244; every eight weeks (about) in 42; every twelve weeks (about) in 49; every six months or over in 30.

A majority of those put down as having attacks weekly or oftener have them anywhere from 50 to 75, or even 100, a day down to two or three a week; most of them with about the latter frequency.

It is safe to say that fully 50 per cent. of all confirmed epileptics have an attack weekly or oftener, generally oftener. A very notable decline begins after the one-week period and continues up to the eight-weeks' period, after which they run on a slightly lower average, during the six months and over period.

In speaking of these periods, we must not be understood as giving them as the exact time that elapses between paroxysms, but as the average time only.

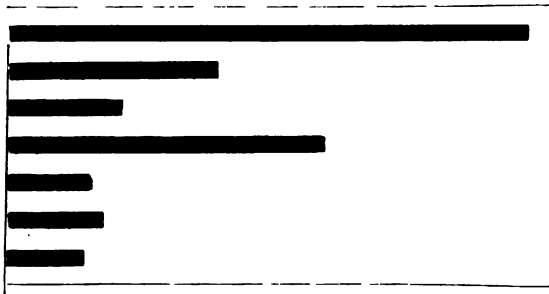
Passing the third-week period, we are at once struck with the great increase in number at the four-weeks' period. This increase is due to the fact that serial attacks in many female epileptics group themselves about the time of the menstrual flow.

Those in the six-months' period (there are a few who go 9 to 12 months and even longer without a seizure) are classed as occasional epileptics. They scarcely ever resemble the idiopathic epileptic in any way, especially in not manifesting his impaired mental characteristics.

The wave of epileptic frequency may later be found to have a causal relationship to more or less rhythmic intoxications of the central nervous system. At present we are ignorant of the nature and mode of action of such intoxicants.

The scientific work to be done in epilepsy that promises most lies at the door of the chemico-clinico-pathologist.

SHOWING FREQUENCY OF EPILEPTIC CONVULSIONS IN 1,374 CASES.



| | | |
|---|---|---|
| Weekly or oftener | 775 | 57 per cent. |
| Two weeks | 173 | 13 per cent. |
| Three weeks | 61 | 4 per cent. |
| Four weeks | 244 | 18 per cent. |
| Eight weeks | 42 | 3 per cent. |
| Twelve weeks | 49 | 4 per cent. |
| Over six months | 30 | 2 per cent. |

**Some Observations on a Crusade Made Against the Mosquito, in Talladega, During the Summer of 1902.**—B. B. Sims says that it is erroneous to suppose that mosquitos fly any distance, or are carried by the wind. They are sometimes carried from one locality to another by railway trains, or sailing vessels. But, as a rule, their breeding places can be found near home, sometimes in the rain water caught by tomato cans, broken bottles, etc., in closed sewers, in rain-filled hollows of trees, in all uncovered water tanks, and by the thousand millions in open cisterns. In one place mosquitos bred in water which had accumulated in sags in the gutters, and were conveyed into the cistern. A pint of kerosene poured into the cistern stopped the nuisance and did not affect the cistern, as it was pumped from the bottom. In the City of Talladega mosquitos were in the habit of breeding by the millions along the banks of two sluggish streams, but last season the infected portion of the city had fewer mosquitos than any other part, due to the fact that it was closely watched and the remedy applied. A man takes a bucket of the oil, and with a dipper dashes it on the stagnant water surface at the rate of one ounce to every fifteen square feet of water surface. A better way is to use a knapsack pump to spray it on. The breezes spread the oil, and the wigglers and adult female mosquitos are done to death. The crusade cost $150 all told; 750 gallons of light fuel oil at 12 cents a gallon were used, and supplied twice a month. The crude oil evaporates less quickly than kerosene. With careful work for three or four years, the author believes that mosquitos can be entirely exterminated in the vicinity.—*The American Practitioner and News.*

# MEDICAL RECORD:

*A Weekly Journal of Medicine and Surgery.*

## THE ACTING ASSISTANT SURGEON, U. S. A.

At last the Tommy Atkins of the medical corps (who does not know how "Its Tommy this an' Tommy that, an' 'Chuck 'im out, the brute, but its savior of 'is country when the guns begin to shoot") has come into his own—as far as credit goes. But from remotest antiquity, republics have not been proverbial for gratitude, and this country is no striking exception to the rule. In the *Journal of the Association of Military Surgeons* for September, Major Azel Ames delivers a vigorous protest against the present status, or rather lack of proper status, of the acting assisting surgeon. Though his duty, authority, prerogatives, pay, and pension are those of an officer, and though the attorney-general and a justice of the Supreme Court have declared his services distinctly "military," and the comptroller of the treasury and the paymaster-general have declared him "a quasi officer," yet Congress, and the War and Treasury Departments withhold from him recognition as an officer. The acting assistant surgeon can share equally with his commissioned brother surgeon the same dangers of wound, disease, capture, imprisonment, hardship and death in camp or hospital, on the march or in the field; the same responsibility for due knowledge of the laws of war and the same amenability to military discipline and punishment; the same responsibility and accountability for the men and property committed to his care, and for the competent administration of hospitals, convalescent camps, transports and hospital ships; but he must not have a commission—that would never do. Yet he may suffer the harshest injustices, among them non-payment of even the poor allowances stipulated in his contract, despite army regulations, and the promises of the surgeon-general when his contract was made. There is hardly one who was in the Spanish war, who is not "out of pocket" to-day by the failure of the government to make good its promises to him. He cannot count on any definite tenure of office, his contract may be annulled at any moment, "for misconduct" or "neglect of duty," his travel allowances being thus cut off, he may thereby be left stranded in farthest Alaska or the Philippines. He, alone of all, who performed military service during the Spanish war, has been refused by Congress the extra compensation granted even to an enlisted man of only a few weeks' service. He reaps no reward for valiant or exceptional service; is not in line with promotion, cannot receive brevet rank or be placed on the retired list if disabled. Those who share with him some especially glorious or beneficent achievement, may receive these rewards, but *he* is debarred therefrom. He cannot, even when ordered to field duty with mounted troops, demand a government mount, or, if furnishing his own horse and equipment, demand forage or farrier service, as of right; though the commissioned assistant surgeon, who rides at his side, may claim both. If stricken down on the field of battle, or by disease, he has no legal claim, and there is no provision for his care when dying, or his treatment or support while lying disabled by wounds or disease. His payment immediately stops, and his country makes no provision for feeding or sheltering him, or giving him medical attendance.

There is no provision for his burial, or for sending home his body. The private whom he was bearing out of the fight upon his back when the same shot killed both is entitled to burial, but the hero who died trying to save him can claim neither. The prime cause of all these hardships is lack of commissioned rank. All of them could be instantly corrected by the according of it, and no valid objection has ever been adduced against its being conferred. Yet all successive efforts during forty years have failed to secure that recognition from Congress. The principal causes of this failure have been lack of effective, organized support from the medical profession and the feeble organization and numbers of those actively engaged in pressing these measures upon Congress; the jealousies of line and staff officers, including some few of the most influential members of the medical staff of the army, who are apprehensive of any action which might tend, in the least, to lesson their importance or exclusiveness, or impair their chances of advancement; the persistent opposition of the secretary of war, *always* most potent in hostility to the proposed legislation; and the undue, almost controlling influence given by Congress to its committees and their reports—and the aid this gives to the official jealousies and antagonisms mentioned, the committees being dominated by the department's recommendation.

When it comes to fixing the responsibility, Major Ames is no respecter of persons. It is hence plain that the responsibility for the grave wrongs, described, and the failure to remedy them, rests primarily with the War Department whose express duty it is to secure to the medical corps of the army, under its charge, the utmost possible efficiency, and to each of its factors exact equity. . . . With Congress lies, then, the second measure of responsibility for the gross injustice of forty years to the acting assistant surgeon.

The remaining measure of responsibility (and it is a large one), rests with the medical profession, the medical colleges, the medical associations, and the medical press of the country . . . for their long neglect of interests so peculiarly their own, and of such vital importance to the whole. The united influence of these bodies, duly organized and exerted, is concededly equal to the accomplishment of almost any desired and laudable object toward which it is directed—with Congress or elsewhere.

"Let it be made a matter of ethics and honor, of professional pride and personal obligation by the members of the medical profession in the United States—vigorously insisted upon by every medical college,

journal, and association—that no medical service with the Army, Navy, or Marine Hospital Corps, shall be accepted by any member except under a commission and equitable conditions, and prompt acquiescence with this most just demand will follow on the part of Congress and the War Department. . . . The acting assistant surgeon has come to stay. For a brief period he went out of existence, only to become at the outbreak of the Spanish war the chief medical reliance of the army. . . . Hitherto the appeals of the surgeon-generals of the army to the patriotism and *esprit de corps* of the medical profession in civil life, in times of need, have met with a fairly prompt response. I venture to believe that—except from considerations of humanity only, in case of brief and dire need after great battles, or in pressing exigencies—a similar response to like appeals, under the same conditions, will never be made. Nor ought it to be, in justice either to the profession, the government, or those called upon."

We think that there is no surer way than for the profession to demand proper recognition, or give no service. The surgeon-general's bureau has before this found itself unable to secure a sufficient number of competent medical men to fill vacancies in the commissioned medical corps, and unless the injustices to the acting assistant surgeon are remedied, the government may find no one coveting the places.

---

## A CHEMICAL HYPOTHESIS REGARDING THE ETIOLOGY OF CANCER.

UNDER this title Dr. John Rogers, Jr., makes, in the August issue of the *Annals of Surgery*, a suggestive contribution to a much-discussed question. He notes the scantiness of literature bearing on the possibility of a chemical or chemico-biological origin of malignant disease. There is a large class of disorders, especially those of which arteriosclerosis is a type, which are but little understood. They may be regarded as expressions of the chemical disorders of advancing life, and are often associated with cancer. Any study of the blood chemistry in the latter condition may be expected, therefore, to shed some light on the former.

The author further notes that while the simpler elements and compounds have been investigated in this direction with a generally negative result practically nothing has been done with reference to the carbohydrates and proteids. It is to these that he calls attention.

Our latest census reports show that the greatest increase in mortality lies in cases of nephritis, apoplexy, influenza, cancer, and heart disease. With the exception of influenza and (for the present) of cancer, all the rest may be said to belong to the connective tissue degenerations. They are evident disorders of metabolism due to some "irritant" in the blood. This group of diseases goes hand in hand with general prosperity, wealth, easy living, strenuous activity, etc., with the implied nervous strain and interference with proper assimilation, oxidation, and excretion. The problem involved is at the bottom essentially a chemical one. "The means other than operative which have been found capable of ameliorating or curing cancer in a few undoubted instances can all be considered chemical in their nature and acting through the blood. The successes in the treatment of sarcoma by the injection of the erysipelas or mixed toxins can only be thus interpreted. To be sure, this is generally considered as evidence of the bacterial nature of the affection; but there is no other proof than analogy, and the cure, though evidently chemical, may be susceptible of a simpler explanation than Ehrlich's theories of the mechanism of immunity would indicate. A possible hint toward the solution is supplied by the fact that during infectious diseases the carbohydrates of the body, and particularly glycogen, are markedly decreased in amount."

So far as the inoculability of cancer is concerned, experimentation and the collective experience of operating surgeons would seem to show that there must exist a proper soil. This must be found in the blood. Glycogen, which is an animal equivalent of starch, is found in all tumors in a quantity varying directly with the malignancy of the disease.

Now traumatism, in some form or other, is about the only (generally accepted) apparently constant cause of cancer, and it is always accompanied by more or less of an attempt at repair by granulations or an infiltration of embryonic round cells. "In constructing an hypothesis for the origin of cancer it is not departing too much from the facts to affirm that these, by their enzyme, assimilate from the blood the carbohydrate to form the glycogen necessary for their life and growth, and by the excess of nutriment present and their own exuberant vitality in given instances proceed to outgrow their natural limits in the shape of malignancy. It is conceivable that ordinarily the residue of the original destruction may supply the food required to start the reparative process, as the enzymes of each part have a selective action, and to complete their function seem to need a food represented in the body of the cells from which they are derived. Ordinarily, when this is exhausted, the enzymes of the surrounding tissues neutralize any excessive cellular reproduction and repair is natural. If there is an excess of food or of enzyme, however, malignant degeneration follows."

Following out the suggestions from the above line of reasoning, the author has examined for the past two years the blood of a considerable number of patients operated on for cancer and other affections. Technical details are described in full. Glucose, being the simplest to investigate, was selected for the first research. Results have seemed to favor the theory of the presence in the blood of a marked glycolytic enzyme, but they do not thus far show that this is in excess in cancer patients. The author adds, however, that as "the only disease which seems to be incompatible with the co-existence of cancer, namely, diabetes, has an excess of glucose in the blood, it is reasonable to suppose that some other carbohydrate ought to be sought for." Finally he concludes that if this line of investigation shall result profitably it will be found that the blood change will prove to be quantitative and not qualitative. The various suggestions he makes are a stimulating summons to the investigators in physiological chemistry.

## SALIVARY DIGESTION IN THE STOMACH.

In the *American Journal of Physiology* for August 1, W. B. Cannon and H. F. Day review the conflicting views on this question, and add their own experimental evidence. The chemical effect of saliva is generally regarded as slight, its action being believed to be soon checked by the acid gastric juice. In 1898, however, Cannon showed, by skiagraphs, that there is a marked difference as regards peristalsis between the cardiac and pyloric ends of the stomach; at the former food is retained in a mass by the tonic contraction of this portion of the gastric wall, while the pyloric portion is undergoing active peristalsis and the contents in that region are, even after thirty minutes, usually far advanced toward chymification. Tests made on dogs and cats one to one and a half hours after eating show that here the contents are strongly acid, and the same is true on the surface of the mass at the cardiac end, but the reaction of the interior of the mass at the cardiac end remained unchanged Further, Heyde, by feeding, and then carefully removing the stomach and freezing, found that the interior of the cardiac mass remained slightly alkaline or neutral for hours. And the same difference in the motility of the two ends of the stomach has been shown to exist in man. The reasons commonly given for considering salivary digestion brief are then by no means convincing, and salivary digestion may continue long uninterrupted in the unmoved mass at the cardiac end. Cannon and Day experimented with cats. Examination of the dried contents of the pyloric and cardiac ends of the stomachs after carbohydrate food mixed with active saliva had been given, showed that at the end of a half hour the percentage of sugar at the two ends was about the same, while at the end of an hour the cardiac end contains about 80 per cent. more sugar per unit of volume than the pyloric end. The absolute amount present in the fundus is, however, really much greater than this ratio would indicate, as the fundus contains, after an ordinary meal, about five times as much food as the pyloric end. After an hour the ratio of the sugar percentages at the two ends begins again to approximate unity, this change being probably due largely to diffusion of sugar into the pyloric end and to some extent to absorption. Position does not very notably affect the differences in sugar production, though when the fundus is lower slightly more sugar is found there. When liquids or small quantities of food are given, or when the stomach is massaged, the amounts of sugar at the two ends are nearly equal. The admixture of proteid with carbohydrate food protects the ptyalin from the action of free hydrochloric acid in the relatively small pyloric portion, and on the surface of the food mass at the cardiac end. The greater mass of the food at the fundus undergoes uninterrupted amylolysis not because the proteid protects the ptyalin, but because here the food is not mixed with gastric juice. Much of the starch not changed to sugar is changed to dextrin, and thus, since dextrin is not easily fermented, the food is saved to the organism. The especial value of this process lies in the fact that it occurs in the greatest degree in the fundus, where the hydrochloric acid inhibiting the action of many of the organized ferments, does not for some time make its appearance. In the early stages of gastric digestion, if food has been properly masticated, the fundus serves chiefly for the action of the ptyalin, the pyloric portion, after a brief stage of salivary digestion, being thenceforward the seat of strictly peptic changes. Later (after two hours or more), when the contents of the fundus become acid, the food in the whole stomach is subjected to proteolytic fermentation. The authors also point out the close agreement between their observations and those of Ellenberger, Hofmeister, and Hofmeier on horses, pigs and rats, in which animals the cardiac end of the stomach is lined to a great extent with pavement epithelium and is supplied with "cardia glands," which are distinguished from the fundus glands by not having an acid secretion; whence, in the absence of gastric secretion, the cardiac end is the seat of prolonged amylolysis. This similarity in salivary digestion between animals without acid secretion at the cardiac end, and animals with free secretion there, indicates that the division of the stomach into two regions with functions chemically different during the early stages of gastric digestion, is a general fact. The important difference is the motor one, the comparative absence of peristalsis at the cardiac end and the consequent quiescence of the food there. It need hardly be added that these results emphasize the extreme importance of insalivation.

---

### A Reformatory Club for Dyspeptics.

The dyspeptic club recently formed in Jersey City aims evidently to create a new "department of the interior," and to manage it on advanced and economic theories. So far there are only fifty-seven members in the organization, although a very much greater number, mostly Americans, are plainly eligible.

We have not been informed of the particular qualifications for membership, but assume that they sum up the main sins of omission in chewing and of commission in bolting various foods. Each member must make quarterly written reports of experiences, and doubtless there will be much comparison of notes, and much detail of hopes deferred and hearts made sick. The diversity of these should certainly give due variety to the sessions. But this is the only way to get at facts. The actions of different foods must be duly estimated. If need be, the old-time theories of indigestion must be combated. Pie and pain, buckwheat and bloat, sausage and suffering, pickle and pang, cabbage and colic, ham and heartburn must show their proper relations. They probably will as the game goes on. The humiliating part of the business is that each culprit must confess to his weak will and his misplaced confidences, while pork, pie, and pudding will still hold their own against odds. If the outcome were not sad it might be humorous. No man, however, with a highly developed indigestive sense can hope to be brilliantly witty or voluntarily truthful. Thus no member should be trusted to give absolutely impartial testimony unless he can prove that he was free from cramp, hyperacidity, headache, or borborygmus when his report was written. Gastralgia is as apt, in a reflex way, to affect the higher moral sense of truth as is a colic to warp sound judgment on the ordinary relation of cause and effect. The only time for good resolutions when the paroxysm is on.

### Radium as a Therapeutic Agent.

The discovery of radium may almost be said to mark an epoch in the history of science. The limit of its potentiality is as yet not nearly known, but the knowledge already gained of its properties clearly distinguish this mineral as in a measure standing apart; and it has been asserted that radium will open up a new field of scientific investigation, perhaps even lead to the isolation of a new group of elements. At the meeting of the New York Academy of Sciences, held recently, radium and the phenomena of radioactivity displayed by the mineral were considered, and a comparison was made between its powers and those of ultraviolet and Röntgen rays. George F. Kunz read a paper on the action of the Röntgen rays, ultraviolet rays, and radium on mineral substances, in one of the lecture rooms of the Natural History Museum. Mr. Kunz also touched briefly on the probable uses of radium in medicine. He said in part: "The invention of Goerl, which has been perfected under the name of the Piffard lamp in the United States by Dr. Henry G. Piffard of New York, is an instrument of great utility, as he has proved it a valuable medical adjunct. This brings to mind a possibility of the utmost importance. There is the possibility that fluorescent substances can be injected into the veins, intestines, etc., or it might be taken in powders or in solution in food, and thus a nearer location effected in organs desired to be examined. The entire tissue structure could then be examined, as well as the bony structure is at present by the Röntgen rays, under the ultraviolet rays." These, however, are but forecasts of what may happen. Some practical work has been done by means of radium. Mr. Mackenzie Davidson of London and Professor Gussenbauer of Vienna have had very successful results in the treatment of rodent cancer by the application of the rays from radium. Mr. Frederick Soddy of University College, London, has suggested a method of applying the rays from radium and thorium in the treatment of consumption. Mr. John Macintyre, surgeon for diseases of the throat and nose, Glasgow Royal Infirmary, contributed an article to the *British Medical Journal* of July 25, in which the therapeutic effects of the salts of radium—so far as is yet known—are well described. He thinks that the study of radium is evidently going to throw a considerable amount of light upon questions hitherto obscure in the region of physics, and it is not altogether improbable that the same thing may be said of it in medicine. According to Mr. Macintyre, three kinds of rays have been already distinguished: (*a*) Infinitely small positively charged atoms of matter flying at great speed, which can be measured, and the result seen by the bombardment on zinc sulphide screens; (*b*) rays which seemingly correspond to the cathodic rays in a Crookes's tube, and also described by Leonard as passing through an aluminum window in the same, and (*c*) rays which evidently correspond to the *x*-rays. The author then gives an account of some cases of lupus and rodent ulcer which yielded to treatment by the salts of radium, and concludes as follows: "A considerable time must yet elapse ere any opinion can be offered about the true value of radium compounds in the treatment of such cases. Even if its therapeutic value be thoroughly established, there will remain the questions of the time taken to produce the desired effect, the kind of cicatrix or covering which forms, and, last, but not least, to what extent they are likely to compete with the *x*-rays, high frequency, or other forces."

Radium, as a therapeutic remedy, is on its trial. There is the possibility, perhaps almost the likelihood, that it may eventually become of inestimable value in medicine, but at present sufficient is not known of its properties to pass a decided opinion. It is in the potential stage, but may emerge now at any time into an actual medical remedy of surpassing merit.

---

### The Checking of Tuberculosis in New York.

Under the heading "The White Plague in New York," the *New York Evening Post*, October 17, gives an excellent sketch of the conditions with regard to consumption which prevail in the city, as well as a history of the disease, the measures which have been put into force to check its spread, and offers suggestions as to the best means of conducting a successful crusade against its inroads. So much has been written and said concerning consumption within the past few years, that it may seem somewhat supererogatory to again bring up the matter. On the principle, however, that "Continual dropping will wear away a stone," so may a persistent ventilation of the subject arouse the apathy of the general public with respect to the menace of tuberculosis. In the past ten years the deaths from various forms of tuberculosis in the Boroughs of Manhattan and The Bronx, have, it is said, averaged about six thousand annually, the great majority being due to pulmonary tuberculosis. This statement alone should be sufficient to excite the alarm of the citizens of New York and to arouse them to resolute action with a view to altering the present condition of affairs. The article in the *Evening Post* expains the indifference of the public as due to the fact that for generations people have been taught to believe that consumption was hereditary, and, when once contracted, incurable; that a certain large portion of each community had always been afflicted with this scourge and always would be; that those who were predestined to contract it would do so, and there wasn't much use in doing anything to prevent it.

Whatever may be the reasons for the disregard with which the ordinary individual regards consumption, one thing would seem to be certain, that if any headway is to be made against the spread of the disease, strict preventive measures must be taken, and that if the inhabitants of a city do not know enough to protect themselves they must be protected against themselves. In the first instance, every effort should be put forth to educate the public as to the nature and best methods of treatment of tuberculosis. At the same time the municipalities of large cities would do well to take immediate steps in the direction of preventive measures.

With perhaps some reservations, the language of the writer in the *Evening Post* in describing the methods most fitting to the situation, meets the circumstances of the case. He writes as follows: "In conducting a campaign against this destroyer of human life in a great city like New York two things are necessary for success. First, the education of the people in regard to the true nature of tuberculosis. Teach the masses that it is not a loathsome, secret, incurable disease reflecting disgrace or discredit upon the individual or his family, but an infectious, communicable disease produced by a germ which is universal, and that it is quite readily curable if taken in time. Inform them that the source of infection is the sputum cast off by the patient, and consequently, of the great responsibility which rests upon each individual to destroy the germs in the expectoration before they can become a source of danger to others. Secondly, a proper provision in the way of hospitals and sana-

toriums for those who have no homes or whose condition and homes are such that they cannot be properly treated, and who are of necessity sources of infection to the healthy. These hospitals should be controlled by a centralized department of the city government, which should have the power to remove to them, forcibly if need be, those people suffering from tuberculosis who cannot be taken care of at home, or those who may wilfully disregard the welfare of others by promiscuous spitting and other filthy habits."

The great and pressing need in New York is the establishment of hospitals and dispensaries for the treatment of phthisical patients. No large city of the world is less provided with such institutions, and until this defect is remedied, but little progress can be made in decreasing the prevalence of the malady. Consumptives in an advanced stage should assuredly be isolated, as these are—and especially in the crowded tenement districts—foci of infection. For the efficacious treatment of persons in the early stages of the disease, the erection of sanatoriums in the country is a *sine quâ non*. Dispensaries, too, might be established in the city itself for the treatment of those who are unable to get away.

Money expended for the relief of those suffering from tuberculosis is, indeed, money well spent. The MEDICAL RECORD has on every available occasion tried to drive home the obvious truth, that it is for the benefit of the citizens as a body that tuberculosis should be strenuously fought. The disease is a menace to all, and the greater the indifference displayed as to its increase, the harder will it be to combat it with any hope of success.

---

## THE HEALTH OF THE BRITISH ARMY IN INDIA IN 1901.

The report of the Imperial Sanitary Commissioners for India for the year 1901 has recently been made public, and a résumé of it appeared in the *British Medical Journal* of September 26. A part of the report is taken up with a brief account of the condition of the British Army in India during 1901.

This should be somewhat interesting to American readers, for purposes of comparison with that portion of the report of the Surgeon-General of the United States Army which refers to the health of the troops in the Philippines. It appears from the report of the British Army in India that in 1901 sickness rates were comparatively low, but invaliding high. The death rate was 12.38 against 14.62 in 1900 and 16.21 in the decennium 1891-1900. Ague and venereal disease were as usual the chief causes of sickness, and enteric fever and hepatic abscess of mortality. There was diminished mortality from cholera, enteric fever, heat stroke, tubercle of lung and abscess of liver and increased mortality from pneumonia and dysentery. Madras and Bombay were the most unhealthy commands, influenza was in excess. There were 12 cases of cholera, all fatal; 30 cases and 3 deaths from smallpox, giving a death rate of 0.05, against a general rate of 0.40. Ague and remittent fever were less prevalent. Five cases of Mediterranean fever were returned. There was a decrease in both morbidity and mortality of enteric fever. The admissions numbered 776, and deaths 202, against 970 and 289 in 1900. The admissions have steadily declined during the last three years. . . . Data bearing on the causation of enteric fever are presented in considerable detail, but no novel conclusion of importance ensues. It is thought that sanitary measures have in part caused the diminution. Only three cases of plague occurred with one death and only one of cerebrospinal fever. There were twenty-eight cases of beriberi, twenty-five of which occurred in Burmah. The mortality from phthisis fell slightly, and that of pneumonia rose a little, as also that of dysentery. Some interesting statistics are given regarding the relation between dysentery and liver abscess. There was a fall from 313 in 1899 and 298 in 1900 to 276 in the admission rate of venereal diseases. Preventive measures are credited with the improvement. The death rate of officers was 11.11 against 11.80 in 1900, and 15.94 in 1891-1900. Of women 17.54 against 12.83 and 16.13, and of children 32.95 against 46.87 and 44.86.

Considering all things, the health of the British Army in India in 1901, and that of the American Army in the Philippines in 1902, was very satisfactory, and goes to show that under good sanitary conditions the white man can live in tropical countries and retain his health and physical vigor.

---

## THE HEALTH OF THE UNITED STATES ARMY.

The annual report of the Surgeon-General of the United States Army for the fiscal year ending June 30, 1903, has just been issued. During the period covered by the report, of the entire army at home and abroad, the white troops showed a hospital admission rate of 17.06 per 1,000, and a death rate of 14.40, while the negro troops had 18.97 admissions per 1,000 and 24.11 deaths per 1,000, and the Malay scouts 17.07 admissions and 24.04 deaths per 1,000. At first sight it would seem as if Asiatic cholera was far more deadly among the negroes and Filipinos than the white troops, the respective cases and death rates being, for the white troops, 4.72 cases and 2.83 deaths per 1,000 of strength; for the negro regiments, 15.68 cases and 7.96 deaths per 1,000, and for the Filipino troops, 16.58 cases and 10.15 deaths per 1,000, but, as Surgeon-General O'Reilly points out, this difference in the rates for sickness and mortality from cholera is mainly explained by the fact that there are a large number of white soldiers in the United States who are not exposed to cholera, and that therefore the rates for the three races do not differ widely.

Excessive consumption of alcohol was responsible for much sickness among the white soldiers, the admission rate for this cause being 24.78 per 1,000, and 11.70 per 1,000 among the negro troops. The Filipinos showed a striking contrast in this respect—out of a force of 5,000 men of this race only three were treated for alcoholism, and the admission rate of the Malay scouts for overindulgence in stimulants was but 0.62 per 1,000. Beriberi was extremely prevalent among the troops of native blood, causing an admission rate among the Malay scouts of 123.92 per 1,000 and a death rate of 6.01 per 1,000. The white soldiers were scarcely at all attacked by this disease, nor were the negroes to any extent.

Reference is made in the report to the successful measures taken to drive out yellow fever from Cuba. An account is also given of the work carried on in the summer of 1902 at army stations of the United States situated in malarious districts with a view of exterminating the mosquitos. The work has been attended with satisfactory results, and will be continued. The methods put into force have consisted of using petroleum on stagnant water, and when practicable, of draining, clearing away underbrush, etc. The casualties in the army during the fiscal year were few in number, twenty soldiers were killed in action, thirty-one committed suicide, and there were twelve homicides.

# News of the Week.

**Conference of Boards of Health.**—The annual conference of State and Provincial Boards of Health was announced to be held October 23 and 24 at Baltimore, Md. The following subjects were to be brought up: "Transportation of the Dead," "The Mosquito and Yellow Fever Question in Havana During the Last Year," and the "Control of Venereal Diseases."

**Free Practice for Osteopaths in New Jersey.**—A curious story from New Jersey is published in the newspapers. It is stated that eight of the leading physicians of Vineland, in that State, had an osteopath arrested on the charge of practising without a license, but the Grand Jury refused to indict for the reason that the majority of the jurors thought a free American citizen should be allowed to call any doctor or physician he wished. There is no New Jersey law under which a license may be granted to an osteopath.

**Yellow Fever in Laredo.**—The fever is now spread over all parts of the town of Laredo, some twenty new cases being reported daily. The total number of cases up to October 18 was 400; of deaths, 27. The city was to have been saturated with oil, all the cesspools and other collections of water being well covered, and it is hoped by this means to put a stop to the increase of the yellow-fever mosquito.

**Cholera in the Holy Land.**—It is reported that cholera has broken out at Bethlehem and the town has been surrounded by a cordon of troops in the hope of preventing the invasion of Jerusalem by the disease.

**Hospital for Contagious Diseases at Greenwich.**—Mr. Robert M. Bruce and his sister Sarah E. Bruce have presented to the town of Greenwich, Conn., a plot of ground with four buildings to be used for a contagious disease and emergency hospital. It is opposite Putnam Cemetery, on high ground, and has one stone house for smallpox and two others for other contagious diseases. The caretaker's house is equipped as an emergency hospital.

**Another Investigation of Randall's Island House of Refuge.**—Not satisfied with the adverse criticisms of the State Fiscal Supervisor, regarding the management of the Randall's Island House of Refuge, the president of the institution has requested the State Board of Charities to cause an investigation of the administration of the institution to be made. The State Board has granted the request, and the board's committee on reformatories will make the investigation at once. The members of this committee are William Rhinelander Stewart, Mrs. Annie G. DePuyster, and Dr. Stephen Smith of New York City.

**"Archives Latines de Médecine et de Biologie"** is the title of a new trilingual monthly medical review, the first number of which was announced for publication on October 15. Beginning with the first of January, 1904, there will be published a bimonthly, eventually perhaps a weekly, supplement containing medical news and information of a practical nature relating to new instruments and remedies, hygiene, sanitary legislation, etc. The original articles will appear in the language of the writers—French, Italian, or Spanish—and each paper will be followed by abstracts in the two other languages. The editor in chief of the new review is Dr. Gustavo Pittaluga of Madrid, with whom are associated Drs. Albert Robin and Raphael Blanchard of Paris, Carlos Maria Cortezo and Santiago Ramón y Cajal of Madrid, Eduardo Maragliano of Genoa, and Battista Grassi of Rome.

**The American Public Health Association.**—The thirty-first annual meeting of this association will be held in Washington on Monday, Tuesday, Wednesday, Thursday, and Friday of next week, October 26, 27, 28, 29, and 30, under the presidency of Surgeon-General Walter Wyman of the Public Health and Marine-Hospital Service. The executive committee has selected the following topics for consideration, but papers will be received upon other sanitary subjects: Purification of Water Supplies, Disposal of Industrial Wastes, Purification and Disposal of Sewage, Disposal of Garbage, Animal Diseases and Animal Food, Car Sanitation, Steamboat and Steamship Sanitation, Etiology of Yellow Fever, Tuberculosis, Plague, Demography and Statistics in Their Sanitary Relation, Cause and Prevention of Infectious Diseases, Infectious Period of Communicable Diseases, Public Health Legislation, Cause and Prevention of Infant Mortality, Disinfectants and Disinfection, Production and Free Distribution of Vaccine, Teaching of Hygiene and Granting of Diploma of Doctor of Public Health, Sanitary Aid Societies, and Canteen in Armies.

**Dr. Louis Rosenwasser** of this city writes: "I would ask you, kindly, to deny in your columns the rumor of my death, which has been current in New York and which has, in fact, been printed in the newspapers. I am in Denver for the benefit of my health, but am far from being dead." We are very pleased to be able to make this announcement on such good authority, and trust that for very many years yet to come Dr. Rosenwasser will be able to characterize any repetition of such a rumor as, in the language of Mark Twain, "grossly exaggerated."

**Hasty Diagnosis of an Ambulance Surgeon.**—Dr. M. Cinberg of this city sends us a protest regarding the snap diagnoses sometimes made by hospital internes. He writes that a patient of his, a business man of the highest probity and respectability, who suffers from a weak heart, was seized the other day with an attack of cardiac syncope in the street. A police officer called an ambulance, the surgeon of which pronounced the man intoxicated, and he was accordingly locked up in the police station. The man was not under the influence of alcohol, and the ignominy of being arrested on a charge of intoxication so disturbed him that his weakened heart is still suffering from the effects of the excitement.

**A New Hospital in Utica.**—Bishop Olmstead of the Episcopal Church, on October 17 laid the cornerstone of the new St. Luke's Home Hospital on Whitesboro street, opposite the State Hospital in Utica. The hospital is the gift of Mr. and Mrs. Frederick T. Proctor of Utica, who purchased the plot, and will build and equip the hospital at a cost of $200,000.

**Tuberculous Teachers Barred.**—The State Board of Health of Indiana has isued orders forbidding the reëmployment of 250 teachers in the public schools who are afflicted with tuberculosis.

**St. Luke's Day Services.**—A special service for physicians was held last Sunday evening in Calvary Protestant Episcopal Church, of which the Rev. Dr. J. Lewis Parks is rector, the service being to mark the feast of St. Luke. Bishop Potter officiated, assisted by the rector and several local clergymen. About two hundred physicians were present. The lesson from Ecclesiasticus, 38, 1–14, beginning "Honor a physician with the honor due unto him for the uses ye may have of him, for the Lord hath created him," was read by Dr. D. B. St. John Roosa, and an address was delivered by Dr. William H. Thomson. Bishop Potter also made a

brief address. The service was preceded by an organ recital by Mr. Lacey-Baker, choir master of Calvary Church.

**Day Patients at the Hospital for Tuberculosis.**—Mr. Homer Folks, Commissioner of Charities of this city, has instituted an improvement in the service of the tuberculosis hospital of the Metropolitan Hospital on Blackwell's Island by the institution of a system of day treatment. At present there are about 330 male and seventy female patients resident at the hospital. A number of female consumptives who would otherwise be benefited by the treatment are, it is believed, precluded from staying at the hospital by the necessity of attending to household duties. A day treatment system has therefore been inaugurated by which women visit the island during the day and are given the open-air treatment, together with the medicines and good food which the regular patients receive. The women return home at night.

**Smallpox in Illinois.**—An outbreak of this disease has occurred at Westfield, Ill. Seventeen patients are now in quarantine in the isolation hospital and others are quarantined in their homes. The public schools have been dismissed indefinitely and all church and public meetings cancelled.

**Philadelphia Pediatric Society.**—At a stated meeting, held October 13, Dr. D. J. Milton Miller exhibited a patient with pseudo-hermaphrodism and an abdominal tumor. The patient was a child two years old, in whom distention of the abdomen had been noticed for ten months, during which time enlargement of the right kidney, of the liver, and of the spleen had been observed. Examination of the blood showed a reduction in hæmoglobin and in the number of red-blood corpuscles and an increase in the number of leucocytes, involving the lymphocytes in a noteworthy degree. The condition was considered to be one of sarcoma of the kidney, with metastatic involvement of the liver, and it was suggested that the splenic tumor might be an independent disorder. In addition, the child presented an hypertrophied clitoris simulating a penis, with a well-marked prepuce, but it contained no urethra, which was, however, present in the usual situation. A vagina was present, but the uterus could not be palpated. The labia majora were greatly enlarged, but they contained no tissue suggestive of testicles. There was also a moderate growth of hair on the vulva. Dr. Herbert V. Carpenter exhibited a patient with bilateral stenosis of Stenson's duct. The condition had been observed only for a period of three weeks, and was characterized by cystic dilatation of the duct visible both externally upon the cheek, and internally within the mouth. It was thought to result from an inflammatory process within the buccal cavity involving the duct by continuity. Dr. Carpenter exhibited also a patient with interesting cardiac signs, a girl of about ten years of age, who had previously had an attack of scarlet fever, followed by muscular and articular pains. The heart was greatly enlarged, and a systolic murmur was audible in the mitral area, and a systolic and a diastolic murmur in the aortic area. There was no œdema and no effusion into serous cavities. The subjective symptoms were comparatively slight, the patient complaining principally of dyspnœa. Dr. I. Valentine Levi read a paper on "Congenital Dilatation of the Colon," reporting the case of a child in whom marked improvement followed the employment of enemata of normal saline solution and administration of nux vomica in increasing doses. In addition to the dilatation of the colon there was also diastasis of the recti muscles and splanchnoptosis. Dr. John H. Jopson presented a communication entitled "Subphrenic Abscess in Children, with the Report of a Case." He pointed out the general rarity of this condition, particularly in children, and he discussed the etiology and treatment. The case reported occurred in a child fifteen months old and the etiology was obscure. The patient had had bronchitis and a slight enterocolitis, and these were thought possible factors. In addition, the responsibility of traumatism as a cause could not be entirely eliminated. The child survived, although the post-operative course of the case was protracted.

**College of Physicians of Philadelphia: Section on General Medicine.**—At a stated meeting, held October 12, Dr. Joseph Sailer exhibited a case of chronic pneumonia in a girl thirteen years old. The patient was a colored child, who gave a history of having had pneumonia four years previously, and who complained of persistent cough. On physical examination there was found impairment of the percussion-resonance, blowing breathing, bronchophony and pectoriloquy and increased vocal resonance and fremitus, On careful observation occasional elevation of temperature was noted, but injection of tuberculin was without effect; and examination of the sputum failed to disclose the presence of tubercle bacilli. The nutrition was little, if at all, affected. Drs. Joseph Sailer and Charles H. Frazier reported a case of typhoid fever, complicated by strangulated Meckel's diverticulum. The patient presented symptoms suggestive of perforation of the bowel, but on operation strangulation of a distended Meckel's diverticulum was found, with some evidences of previous but not of present peritonitis. There were no indications of obstruction of the bowel, and no noteworthy leucocytosis. The diverticulum was ligated and inverted into the intestine, but on account of the poor condition of the patient, further search for a perforation was not made. Death resulted, and on post-mortem examination fluid effusion into the peritoneal cavity was found, together with other evidences of recent peritonitis, but most careful search failed to disclose the presence of any perforation. It is believed that the primary changes in the diverticulum had begun at an earlier date, when the patient was thought to have had an attack of biliary colic, and that infection, perhaps with typhoid bacilli, had taken place during the fatal illness. Dr. David L. Edsall reported a small epidemic of staphylococcus infection of the skin occurring in cases of typhoid fever. Furuncles and vesicles developed, principally in and adjacent to the sacral region in a series of half a dozen cases of typhoid fever in close proximity, and it was thought that the infection must be conveyed by attendants, perhaps in the process of bathing, or in the use of the bed-pan or the like. Upon the institution of prophylactic measures directed toward these factors, no further cases occurred, though at a later date there was some recurrence. Dr. David Riesman made a clinical report of a case of horizontal dilatation of the left auricle (Ewart). He referred to the cases reported by Ewart and Owen, in which the condition described was observed during life and confirmed on post-mortem examination. Among the symptoms were marked enlargement of the heart, particularly at the base and to the right, with systolic pulsation, and also pulsation of the liver, without pulsation in the vessels of the neck, ascites or œdema of the lower extremities, and with murmurs of mitral obstruction and insufficiency. Dr. Wm. Pepper reported a case of aneurysm of the abdominal aorta and formation of a large adventitious sac. The patient was a shoemaker, with a history of syphillis, and to this, together with the

pressure of his tools upon his abdomen, was attributed the origin of the condition. Dr. Alfred Stengel presented a communication entitled "Desquamation after Typhoid Fever, with Particular Reference to the Occurrence of this Condition in Children." He reported a series in observations in which desquamation, either furfuraceous or squamous, was found in more than 50 per cent. of the cases, principally late in the disease, at or near convalescence. He was inclined to attribute the peculiarity to bathing, although other observers thought sudamina and perhaps trophic conditions might be responsible in some instances. It seems to occur with peculiar readiness in children, perhaps on account of the delicacy of their skin.

**Dr. Hilary M. Christian,** surgeon in charge of the Genito-urinary Dispensary of the University of Pennsylvania, has been recently elected Clinical Professor of Genito-urinary Diseases, at the Medico-Chirurgical College of Philadelphia.

**Disappearance of a London Physician.**—The body of Miss Hickman, the woman physician of London, who disappeared suddenly and mysteriously two months ago, has been found in an unfrequented part of Richmond Park. The throat had apparently been cut, though the body was so decomposed that it was difficult to determine whether this was so, or whether the head had been separated by the gnawing of rats. Miss Hickman, who was a fully qualified doctor of medicine, twenty-nine years old, had been performing her duties at the Royal Free Hospital on the afternoon of August 15, when she left the hospital. Since that time the police of the whole country have unavailingly searched for her. She took nothing with her except a few pounds sterling. No reason is known for her disappearance. The body was identified by a medal which she had won in a swimming competition and by her ambulance cross.

**Obituary Notes.**—Dr. JEAN CHAUVEAU died on October 17, at his home in this city. He was born in the West Indies seventy-two years ago, was graduated from the Geneva Medical College in 1853, and then came to this city. He celebrated his fiftieth anniversary as a physician last June. He had been the attending physician at the French Hospital in West Thirty-fourth street since it was opened in 1883, and he was the correspondent of the French Medico-Legal Society and a member of the New York State Medical Association, the New York Academy of Medicine, the Neurological Society, the Medical Society of the County of New York, and other societies. Dr. Chauveau leaves a widow and a son, Dr. J. F. Chauveau, Jr.

Dr. JONATHAN TAFT, one of the best-known dentists in the country, and founder and for many years dean of the dental department at the University of Michigan, died at his home in Ann Arbor on October 15.

Dr. H. M. ALEXANDER died on October 14, at Conewago, Pa., at the age of fifty-two years. He was the proprietor of the Lancaster County Vaccine Farms.

Dr. ROBERT ABERDEIN of Syracuse died at the Hospital of the Good Shepherd in that city, on October 18. He was born in Chippewa, Ontario, on December 7, 1845. He was a graduate of the University of Toronto and of the Baltimore Hospital Medical School in 1867. He practised in Syracuse from 1875 until three years ago, when the illness from which he died attacked him. He was a Fellow of the Royal Microscopical Society, a member of the American Microscopical Society, and a member of the Onondaga County Medical Society and of the American Medical Association.

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

OPENING OF THE WINTER SESSION—REGISTRAR-GENERAL'S REPORT—IRISH DISPENSARY DOCTORS—HOSPITALS AND SHOPPING—TSETSE FLIES—RUGE'S MALARIA—LAFER'S MYCOLOGY.

LONDON, October 2, 1903.

THE long vacation is over. The winter session began yesterday. The opening day at the schools has lost a good deal of its old charm since a number of them replaced the time-honored Introductory lecture by a dinner or conversazione. Some, however, stand on the ancient ways. King's College secured Sir J. A. Cockburn as lecturer, and King's being one of the centers of the higher education in all directions, he took an extended view of his subject, pointing out that the world-wide possessions of Great Britain presented an unparalleled field of activity for every well-equipped medical student. Science owed much to the facilities for research and travel afforded by such a vast area. Cables and steam had, as it were, contracted the surface of the earth so that the nation no longer sufficed as the unit of power and all aimed at empire. Future rivalries would be between empires of which nations were component parts, and he looked with confidence to the continued progress of the Anglo-Saxon race.

At St. George's Hospital Dr. Dakin took a more medical view of his position, and having welcomed the new students, told them a doctor's life involved the greatest strain on the physical, mental, and moral powers. But it was extremely interesting, and after a day's work well done the doctor might seek his bed with a clearer conscience than many of his fellow citizens. The persons who were not suited to the medical life were those who were cursed with a despondent mind, those who were fit for parts more of a lighter character, and those of not quite perfect honesty of purpose. Extreme ability was not indispensable, though it was certainly most useful at times. The greatest success, at any rate from a financial point of view, had been known to be obtained in its complete absence. But though we see the wicked man flourish in the proverbial manner it did not last long, unless he was a very clever knave indeed. Apart from abstract principles of morality, he had no doubt it paid in their profession to be straight. In addition to honesty, a fair degree of intelligence and average common sense, the lecturer thought a sense of humor was very desirable. The greatest difficulty was often to keep abreast of the special knowledge and power of original research possessed by one's patients. Only by severe application and constant study of foreign literature, combined with some evasions, could the doctor bring himself on the platform of certain patients and convince them of his fitness to carry out their suggestions as to the proper treatment of their unique cases. When the laughter at this sally subsided, Dr. Dakin proceeded to discourse on the progress of gynecology, and midwifery became the obstetric physician to the hospital.

So, too, at the Middlesex Hospital, Mr. William Hern, the dental surgeon, took for his text the care of the teeth. He inveighed against the tendency to ignore minor causes of disease and urged that satisfaction at possessing a remedy for a disease should not lead to neglect of the means for preventing it. To this end medical men should continue to impress on the people the observance of hygienic principles. In a recent investigation 80 per cent. of the children in industrial schools were found to be suffering from dental caries. Thousands yearly sought the help of hospitals for ailments due to oral sepsis, caries, or loss of teeth—the consequences of neglect in childhood. He thought the State should organize some system of supervision and instruction of the children on the importance of preserving their teeth, and the means of doing so.

At the School of Medicine for Women, Dr. Elizabeth Pace traced the history of the medical education of women in Great Britain from the time when Dr. E. Blackwell, some sixty years ago, began her study and became the first woman doctor of modern times. This London school was opened in 1874, and three years later the Royal Free Hospital was opened to the pupils for clinical work and has continued in intimate association ever since.

At St. Mary's, Dr. V. Warren Low, who has served in South Africa, and is now surgeon and joint lecturer on surgery at the hospital, gave an address on the relation of the military medical service to the civil profession. He mentioned that in the reign of Edward II there was a chirurgeon with every 1,900 men who had four pence per day, but the service only dates practically from the regimental surgeon who held the King's commission in the same way as the military officers, and was as much a

art of the regiment as its colonel. From this he traced riefly the history of the service to the establishment of he Royal Army Medical Corps, and commented on the act that it did not break down in spite of inadequacy. ut the lavish expenditure was the result of want of reparation. Some 500 extra officers would be required efore three army corps could take the field, and public pinion has not insisted on provision in peace for a time f war. Dr. Warren proposed a reserve of civilian practioners to be paid a retaining fee according to grade, to e properly trained to be called on in national emergenies, to rank with the Royal Army Medical Corps. He uggested three grades: (*a*) Men qualified for three ears or less; (*b*) surgeons on the junior staff of hositals; (*c*) a few of the heads of the profession—one to be n eminent pathologist. This reserve would supplement he Royal Army Medical Corps and work with it. What ill the War Office say?

At Charing Cross Hospital the old Introductory has een given up, but Sir Charles Wyndham came to distribute the prizes, and delivered a pleasant little address, n which he said he formerly had the honor of belonging o the profession, though the theater in which he now perates is not surgical. But years could not break the ond between him and the profession. He would not ongratulate the prizemen, for they had given hostages o fortune and had to live up to their position. To all the tudents the first counsel he would give was to be loyal to he high ideals of their calling, and no ideal could be too igh. He urged the importance, nobility, and sanctity of hat calling. Watchfulness, care, and discretion should e exercised and their position never misused. Science lemanded moral courage in not disguising the truth. ilence was not always golden, and he believed in stern lenunciation and the caustic criticism of an Abernethy, hen fashionable complaints were brought on by folly hich could, perhaps, be prevented by timely warning. he achievements of the past were nothing to the promise f the future.

The Royal Veterinary College calls for a notice here, as it secured Mr. J. Astley Bloxam, formerly surgeon to Charing Cross Hospital, to give an address. He said that the purpose of the foundation, a century ago, had been adhered to. It was to bring into a regular system that branch of medicine which related to diseases of animals. He traced some of the early history of the college and referred to the distinguished men who had occupied the post of its principal. The first diploma granted was dated 1794, and on it were the signatures of those great surgeons, Henry Cline, John Abernethy, Ashley Cooper and Everard Home. Many are the medical problems awaiting solution in which the veterinary surgeon can coöperate, such as those presented by new growths. The causes of anthrax, glanders, and swine fever were known, but the contagion of others has to be discovered. Rabies he hoped had been stamped out, but it was premature to conclude that such is the case.

Mr. Bloxam held that the State must follow the example of other countries and recognize the importance to mankind of veterinary science. He advocated the establishment of a farm for convalescing animals and a place where sound animals could be studied, as well as endowment for the college.

The Registrar-General's sixty-fourth annual report has appeared at last. It is for the year 1901, and the delay in issuing it certainly detracts from its interest, and, in some respects, from its value. The Registrar-General seems to have taken a hint from the fact that his dilatoriness was the subject of remarks in the House of Commons, and he offers in the new blue book his explanation. It is said that the process of compilation can only be commenced after the enormous number of entries have been subjected to close scrutiny and the numerous points of doubt have been cleared up by correspondence. Further, that a large part of the work can be performed only by specially trained clerks—an assertion which rather surprises one and makes one think that the head of this office ought himself to have been an expert, and not a mere political placeman, as I wrote to you when he was appointed. It is further stated that this year an enormous number of death rates relating to the years 1891 to 1900 has been required in accordance with the detailed results of the recent census, and a rearrangement of the form of the statistics of causes of death. This last point gives one pause as to the possibility of comparing these statistics with those of previous returns. I am glad, therefore, to note that the medical superintendent of these statistics (Dr. Tatham) considers the records are comparable with those of preceding reports. Nevertheless, the disappearance of some of the old headings, such as zymotic, will certainly cause some embarrassment to those who only consult the statistics occasionally. Yet some change seems necessary for its purpose, though it is not offered as a scientific nomenclature, but only as a convenient tabulation, and that also more or less provisional. As I have commented on the delay in the issue of the annual report, I would add that the "weekly return" is brought out with great regularity and shows the mortality of the great towns. The quarterly return appears about a month after the close of each quarter and relates to the whole of England and Wales. Both these are of great use to sanitarians and others.

The Irish dispensary doctor's lot is a hard one. This is always admitted by those who could improve it but who never trouble to do so. At first the law was carried out, with a view of fulfilling the intention to afford relief to the real paupers. But gradually abuses crept in until any one could demand attendance on production of a ticket, and as such a ticket could be usually had for the asking, any one who was not ashamed to receive gratuitous medical assistance was able to call upon the dispensary doctor for his services. The abuse has at last become so flagrant that some of the newspapers are calling for its redress, but the official seems unable to comprehend that the doctors may really unite, as they threaten to do. At present they are asking for some form of inquiry. If this is refused, there will be definite demands and an appeal to Parliament. Many and curious are the schemes proposed for raising money for hospitals. We have a Sunday Fund, a Saturday Fund, and a League of Mercy, besides all sorts of entertainments. Now we are threatened with a "Hospital Shopping Day" to assist King Edward's Fund. The proposal is to do our shopping as far as possible on a fixed day, at shops where a percentage of the day's takings is promised to be handed over to the King's Fund for the hospitals. Some proprietors of large establishments have already joined the scheme, and the first day for putting it in force is fixed for November 3. I suppose the shopkeepers think that it will be a good advertisement. But there are strong objections expressed by not a few, and yesterday the Drapers' Chamber of Trade passed a resolution of strong disapproval of the innovation, which, if agreed to, the resolution said, might be repeated by other institutions.

An important volume has been issued by the authorities of the British Museum, viz., "A Monograph of the Tsetse Flies (Genus Glossina, Westwood)." It is based on the collection in the museum, and written by Ernest Edward Austin, with a chapter on the mouth parts by H. J. Hansen, Ph.D. It is illustrated with nine plates by Terzi, and extends to 330 pages, royal 8vo. Mr. Austin, you will remember, identified the tsetse from Uganda as Glossina palpalis.

A translation of Reinhold Ruge's "Introduction to the Study of Malarial Diseases" has appeared. It is a book of 138 pages, designed to assist medical men who have not the opportunity of consulting others, as in some colonies or on ships. There are two plates of the parasites and numerous woodcuts and temperature charts.

Dr. Lafar's "Technical Mycology" is being translated by Mr. C. T. C. Salter. It is devoted to the study of microorganisms as utilized in the arts and manufactures. The first volume is on Schizomycetic Fermentation and extends to above 500 8vo pages.

---

## LETTER FROM BEIRUT.

(From Our Special Correspondent.)

BEIRUT, September 7, 1903.

TO-NIGHT Beirut is like unto a city of the dead. For some time past a species of *vendetta* has been going on—Christian against Moslem. Yesterday this culminated in a party fight at Mossaitby and Mazra, suburbs on the south of the Beirut promontory. At first a fight, it looked dangerously like degenerating into a massacre; and many acts are authenticated on the part of the Moslems (who, it appears, though far superior in numbers, would not obtain possession of the Christian quarters at Mazra and Mossaitby) that could only be characterized as butchery in cold blood. A young girl of good family—shot twice through the chest—had her hands cut off in order to obtain possession of the bangles she wore. An old man left alone because "he was not worth killing." Another old man—less fortunate than the former—cut down as he was relieving nature in his watercloset. One man cut in four pieces before his wife and family because he defended his house. Dynamite was freely used, and some women were killed by falling houses. A church was entered and desecrated. An inoffensive priest was deliberately shot, and, that not being effectual, he was finished by a bomb thrown at him. The Moslem mob then approached Beirut and looted and killed in a quarter called Ras el Nebba. A doctor's house was plundered near this quarter, the guardian (the doctor being on his summer visit to the mountains) being immediately cut down on offering resistance. Most of the Christian inhabitants that remained during the summer months

have taken refuge in Lebanon, where, of course, they are under the protection of the six European powers, and the Moslem is in subjection to the laws of rule and order. The shops are closed and will probably remain so, and business will be at a standstill for some days to come. The Vali is either incapable or guilty. Anyway he seems utterly worthless in the emergency. For some time past—say for the last fifteen days—murders and attempted murders have been of daily occurrence. There were shooting and stabbing in open daylight: the assassins, or would-be-assassin was *non est*, and the authorities went on the even tenor of their way—some hint darkly that they accepted an occasional *honorarium* for their generous ineptitude. Be that as it may, things have come to a climax, and there is what might be called a reflection of Macedonia in the clouds of Beirut at present.

The dyspeptic among us—particularly those of us who have been suffering from the formidable so-called hypersthenic type of that malady, must look upon these riots and their accompaniments as not an unmixed evil. We have been put on a system of enforced starvation for the last two days. No meat in the market, and very few vegetables; no eggs, and milk is beyond price. However, we have still bread and water diet to look forward to, so long as flour holds out and the bakers don't close their ovens.

Our streets have been or are being paved, as we said in a former letter. Those of them that have already been paved are already showing signs of decrepitude and incipient old age. Either the engineering was bad or the job was one of those cheap and nasty ones in which the amount expended does not steer a direct course to the laborer's pocket. With good intent, good purpose, and good accomplishment, Beirut, as it stands, gives all facilities to competent men—engineers and sanitarians—to make it a model for health, comfort, and cleanliness.

We are always hopeful here—perhaps it is due to sunlight and bright skies. But things look dark enough just now.

We give a few undated details: An English consul stopped and insulted in the principal square of the town in open daylight; an English vice-consul held up, the sleeve of his coat cut off, and his watch taken from him—in each instance *no notice taken*, an English archdeacon shot at—result as above; an American vice-consul twice attacked for presumable purposes of robbery, and a third time shot at evidently with intent to kill. In the latter instance some notice *has* been taken, and, as we write, there are two American frigates lying in our roadstead.

So far cholera and plague have given us a wide berth. True it is noised abroad that they are in our vicinity, and we are happy in that they have not reached our very doors.

We have, however, to put up with the constant company of a canker that is eating at the root of all things here—fanaticism, to wit, with its accompaniments. Against this novel sickness there is no remedy. It may wear itself out; but while it exists there will be always all things rotten in this Kingdom of Beirut.

---

# Progress of Medical Science.

*Boston Medical and Surgical Journal, Oct.* 15, 1903.

**The Formation of Loose Cartilages in the Knee-joint.**—E. A. Codman states that the life history of the loose cartilage must comprise two injuries, one to depress it and one to free it. As a matter of fact this is often the case, although the first injury is forgotten. Torn or displaced semilunars do not show in the *x*-ray. The writer calls attention to the formation of the "joint mice," cartilage-like bodies varying in size from that of a small bean to that of an oyster, and being either free in the joint or held by a pedicle of light adhesions to the capsule. Such bodies are common enough, and in many cases cause little or no trouble, while in others much annoyance is produced by locking of the joint and the production of a chronic synovitis. At this time the patient usually comes to operation. A small incision in the capsule is made and the mouse pops out. The result is usually a perfect cure. As to the origin of these bodies the writer believes that they are actual bits of articular cartilage set free by trauma, at least in the vast majority of cases. In the majority of these mice, one side is of cartilage and the other of modified spongy bone. Such bodies show in the *x*-ray, for they consist in part of bone. The practical surgical point to be learned from all this is that in these operations the articular surface of the internal condyle should, if possible, be inspected. When the knee is flexed, the internal cartilaginous surface is exposed to violence. The writer has experimented on the cadaver, and found that a blow merely dented in the articular surface in just such a manner as a fragment is depressed in a skull fracture. This fragment can be easily pried out. In every case it brings with it a lamina of spongy bone.

**Parasyphilitic Affections or Remote Effects of Syphilis.**—Abner Post gives two principal characteristics which establish a well-marked line of demarcation between the affections called syphilitic and the parasyphilitic affections. The latter are not referred necessarily to syphilis as a cause, while the purely syphilitic affections never exist without syphilis as a cause. The latter are not influenced by mercury and iodide of potassium as are the true syphilitic affections. The most important members of the parasyphilitic group as sequels of acquired syphilis, are locomotor ataxia, general paralysis, and epilepsy. Tabes and general paralysis seem to be two topographical manifestations of one and the same malady. When it locates itself exclusively or predominantly upon the cord it constitutes tabes. When it locates itself upon the brain, it constitutes general paralysis. When it affects both cord and brain, it constitutes a hybrid type to which the name cerebrospinal tabes would be applicable. Epilepsy often follows syphilis, or at least epileptiform attacks are symptoms in the evolution of a cerebral syphilis. As such they are the direct results of syphilis and to be classed with other tertiary lesions, but now and then there occurs an epilepsy not conjoined with other syphilitic lesions, which Fournier believes should, as we are ignorant of its true nature, be classed with parasyphilitic affections. A curious form of progressive muscular atrophy deserves a place in this category. Antisyphilitic agents exercise no influence upon the disease. There are many cases of hysteria in the children of syphilitic parents, but the relation of cause and effect is not so sure. Also of epilepsy it may be said of certain cases in heredosyphilitics that while many of them are due to syphilitic lesions there are many others in which the convulsive seizures are the only symptoms, and in which it is impossible to say whether there are syphilitic lesions, whether syphilis is a provoking cause, or whether syphilis bears no relationship. More certainty can be felt as regards tabes and general paralysis. The writer does not consider this as a final account of the subject of parasyphilitic affections. It may be necessary in the future to add or subtract from it. It may be that it can never be completed until the bacteriology of the disease is known, and enables us to distinguish between diseases which are syphilitic by nature and those which are parasyphilitic.

*Journal of the American Medical Association, Oct.* 17, 1903.

**Hygiene of Young Girls.**—J. H. Carstens says that in many cases it is the mother that must be treated rather than the daughter. She must be taught to bring up her daughters properly. In case of girls who are early compelled to go to work, modern laws have done much to help their condition. Such laws as refer to regulating the hours of labor, suitable ventilation, proper toilet facilities, and opportunities for getting food at proper intervals should be encouraged. Gymnastic exercise is good but should be under medical regulation. In this way menstruation will, unless there be organic defects, take care of itself. If the physical condition is below par, care should be taken not to overstimulate the mental faculties. No one set of rules will answer for every case.

**Pelvic Diseases in Young Girls.**—F. F. Lawrence presents the following conclusions: (1) All cases, whether in young girls or in older women, in which menstrual pain, intermenstrual or premenstrual pain is a prominent symptom should be subjected to careful and thorough examination to determine its cause. (2) No leucorrhœa should be permitted to pass unnoticed or treated by such "slipshod" methods as ordering a douche, giving medicine, etc., without first ascertaining its cause In all cases in which discharge is purulent a microscopical examination should be made to determine presence or absence of gonococci, tubercle bacilli, or other important septic organisms. (3) All cases of excessive flowing, intermenstrual hemorrhage, or prolonged menstruation should be thoroughly examined. (4) In all cases in which amenorrhœa exists every effort should be made to find the cause. (5) In young girls subjects of neurotic troubles which develop at puberty or occur with each menstrual epoch, a careful and thorough examination of the pelvis will often reveal the cause. (6) If menstrual pain, irregularity, leucorrhœa, and neurotic disturbances follow the exanthemata, a pelvic examination is imperatively demanded. (7) In all virgins the rectobimanual examination should be used—the vaginal touch only being used when absolutely necessary.

*Medical News, October* 17, 1903.

**The Importance of the Surgical Treatment of Chronic Middle-ear Suppuration.**—Edward Bradford Dench recapitulates as follows: In all cases of persistent and profuse aural discharge the radical operation is the operation

of election. In cases of recurrent aural discharge associated with lesions of the upper airtract this tract should first be put in a normal condition. In case of persistent but slight discharge from the ear the operator may advise the removal of the carious ossicles together with thorough curettement of the middle ear through the external auditory meatus. It should always be explained to the patient, however, that this operation is a tentative one, and that the more radical procedure may be necessary later.

**Early Recognitions of Impending Obstetric Accidents.**—Joseph B. De Lee first considers impending eclampsia. In the first place the family history must be learned, then the personal history of the patient: whether there has been any infectious disease leaving damaged kidneys or a deranged liver. All these conditions indicate the possibility of eclampsia. As a routine practice the urine of pregnant women should be systematically examined. The presence of albumin and casts is a most reliable sign of threatening danger, and should always be an object of careful search during pregnancy. Next in importance is the amount of urine passed daily, together with the specific gravity. That is, the daily amount of total solids excreted. Normally the pregnant woman passes sixty ounces of urine a day with a specific gravity of 1014, giving her a normal excretion of solids. The patient may pass 30 ounces of urine with high specific gravity and be well, or more urine with low specific gravity. The writer believes that the urea index is of least importance. He places more reliance on a careful study of the patient as just described, and a watch for the signs of deficient excretion or of toxæmia. Every pregnant woman should be fortified against postpartum hemorrhage and placenta prævia. As to contracted pelves, the routine examination of the pregnant woman should include, first, the size, shape, and inclination of the pelvis, and, second, the size and development of the child. Should there be any doubt about the child being able to pass through the pelvis the patient should be examined each week. A woman with a pelvis slightly contracted should not be allowed to go over time. The writer always visits each woman shortly before her labor to determine by external examination the position of the child, the engagement of the head, the presence of twins, etc. During labor much can be done to anticipate impending danger to the fœtus. The fetal heart tones give the most reliable evidence, and much can be learned by studying their frequency, rhythm, and quality. The physician should be in a state of armed watchfulness to foresee far in advance impending accidents.

**Bronchiectasis in the Tuberculous.**—S. Edwin Solly declares that as a fundamental principle it may be stated that tuberculosis may occur as a complication of bronchiectasis, but that practically bronchiectasis of large areas never arises as a complication of tuberculosis. This is an axiom stated by Hoffmann. Moreover, he admits that small bronchiectatic areas with special clinical importance are not infrequent. Also that large areas sometimes occur in the tuberculous in cases in which there have been circumscribed processes in the apices and a tendency to recovery by subsequent fibrosis, and only under such circumstances. In this category the case reported apparently falls, in so far as there was undoubtedly a previous tuberculosis at the right apex and in the bronchial glands, but that the bronchiectasis was caused, or at least, brought into prominence by the pressure of the swollen bronchial glands rather than by the fibroid changes of the lung tissue. The patient was a woman forty-eight years old, subject to frequent attacks of bronchitis. There came a period when there was a good deal of spasmodic coughing without expectoration and a general depression of health, but no fever. Then came a continuous fever, and not intermittent, like hectic cough diminished, and still no expectoration; emaciation, general depression, gastro-intestinal indigestion, and no relief of the fever from treatment. Iodide of potash gave relief. It apparently effected its purpose by causing an absorption of lymph and a free escape of purulent tuberculous matter, which had evidently been compressed in some sac or tube. Resulting, there was a subsidence of the high continuous fever, and in its place an ordinary mild hectic, with free expectoration and moderate cough, which was interrupted several times by a cessation of the cough and expectoration, followed by a return of the high continuous fever, which was not relieved until the iodide of potash was given freely again. Finally a period of six weeks of almost steady improvement with free but slightly diminished cough and expectoration. The local pulmonary signs indicated an old inactive tuberculous process at the right apex and solidification around the root of the right lung, with slight incomplete atelectasis of the right lower lobe. The writer believes that at some indeterminate time in the patient's history there had been an acute tuberculous infiltration at the right apex which had been arrested by fibrosis; and also tuberculous infiltration of the bronchial glands probably preceding the apical disease.

*New York Medical Journal, October 17, 1903.*

**The Treatment of Convergent Strabismus.**—W. G. Craig offers the following propositions: (1) The earlier the child is seen, the better the prospect for a cure. (2) The vision of squinting eyes can in a majority of cases be improved and some function restored if treatment is begun early. (3) A small percentage of cases of convergent squint can be cured by mydriatics, glasses, and proper exercises, alone without operation. (4) The correction by non-operative methods is much to be preferred, as the motility of the eye is more perfect and the deformity produced by sinking of the caruncle is avoided. (5) Operative procedures should be employed in those cases in which non-operative treatment after a thorough trial has failed, and in those cases in adults in which we operate for the cosmetic effect.

**Left-sided Appendicitis.**—E. W. Holmes gives the autopsy findings on two white male adults. In one the appendix was attached just below the ileocæcal valve (which was on the left side of the fourth lumbar vertebral and pointed upward and backward toward the liver; in the other the appendix was a little to the left of the median line, entering the cæcum as it rested on the promontory of the sacrum, the base being on a line between the anterior superior spinous processes of the ilium, the body running upward in front of the sigmoid mesocolon, then turning downward in front of the omega loop in front of the brim of the pelvis. In both there were various abnormal displacements of the viscera, explainable on embryological grounds. Appendix pain may be reflected to the left side when the organ itself is normally located. According to the author, the McBurney point should be fixed with regard to the site of the base of the appendix rather than rigidly in relation to the external anatomical structures.

**The Value of Albuminuria in Differentiating Pyelitis from Cystitis.**—T. R. Brown reports nine cases, which he claims justify his contention that pyuria due to a cystitis, even if of high grade, is associated with but a small amount of albumin if the urine is examined immediately after catheterization, if the pyuria is not accompanied by hæmaturia. On the other hand, in all cases of pyelitis, even if the grade of pyuria is low, there is always, or at least almost always, a considerable quantity of albumin present. In some cases the presence of casts and epithelial cells from the renal pelvis may help in arriving at a correct diagnosis, but in the vast majority of cases no help can be derived from the microscopical examination, and we must depend largely upon other means for arriving at a correct diagnosis. In the determination of the relationship between the grades of pyuria and albuminuria there is a ready and simple means of differentiating pyelitis and cystitis. In other words, in any case in which on association with pyuria there is a considerable albuminuria, there is a great probability, if not a certainty, that an infection of the kidney is present, except in those cases in which the albumin present is referable to a nephritis, which is also present—in which case obviously the presence of casts on microscopical examination will demonstrate to us what is the cause of the albuminuria—or to a high grade of hæmaturia.

*American Medicine, October 17, 1903.*

**Cardiac Complications of Influenza.**—E. G. Wood declares that in the number and protean character of its complications and sequels influenza probably ranks second only to typhoid fever. Grippal pericarditis shows anatomical changes similar to those found in other forms of the disease. Endocarditisis generally thought to be a rare complication of influenza. It may be simple or ulcerative or malignant. Myocardial changes are common in influenza. The influenza bacillus elaborates a poison which, circulating in the blood in sufficient quantities, acts as a powerful heart depressant and modifier of the nutrition of the heart muscle. Among the functional cardiac disturbances following influenza are palpitation, irregularity, bradycardia and tachycardia. Fortunately these disturbances usually disappear in a few weeks, but in some instances they have persisted even for years.

**The Interrelations of Diabetes and Other Constitutional States.**—George F. Butler says that the great error ruling conceptions of disease in its clinical and therapeutic aspects is that which fixes upon one symptom as a test of disease rather than the symptom complex. Every one of the febrile conditions may be glycosuric. With delirium tremens and the confusal insanities, temporary glycosuria may at times be coincident. Pregnancy is often attended by glycosuria. In many neuroses glycosuria may disappear just previous to cerebral complications. Diabetic vertigo often assumes an elipeptoid character. Asthma, exophthalmic goiter, and other respiratory neuroses are not infrequently temporary expressions of

diabetes. The most serious symptom of diabetes is coma. The etiologic importance of coma lies first in the condition of the patient at the time of the attack, and depends largely upon the condition of the emunctories. Another phase of etiologic moment is the condition of the arteries. There are many eye, ear, nose, throat, gum, skin, and genito-urinary phenomena found in diabetes which bear some relationship to the disease. They are an outcome of diabetes and modify it or are modified by it. Finally they may be mere coincidences. Most cases of diabetes are at first expressions of nutritional and assimilational instability.

**Antistreptococcic Serum in the Treatment of Inflammatory Rheumatism and Other Diseases; with Report of Cases.**—G. H. Sherman has given antistreptococcic serum in all the stages of erysipelas always with good results in proportion to the time and amount given, obtaining, however, the best results when given early. He reports numerous cases of inflammatory rheumatism. His experience in their treatment extends over a period of twenty years. All of these cases, with possibly one exception, give a typical history of inflammatory rheumatism and some showed early evidences of more than the usual severity. There were no cases of prolonged convalesence or general debility after the rheumatic symptoms disappeared. A characteristic feature of all these patients was the evident good condition of the digestive organs as shown by their general expression of having a good appetite and being able to eat well after the serum was given. None of the patients developed heart complications, for the disease was cut short before heart involvements usually take place. While the serum treatment was used no other treatment was resorted to. The writer concludes that when we consider the results obtained in these cases, from a marked improvement after the first and second dose to a complete recovery in a comparatively short time, the therapeutic value of antistreptococcic serum in treating inflammatory rheumatism becomes strikingly apparent.

*The Lancet, October* 10, 1903.

**Diabetic Intraocular Lipæmia, in Which the Blood Was Examined During Life.**—The patient of W. H. White was a man of twenty-six years, admitted to hospital for hunger, thirst, polyuria emaciation and weakness. He was placed on the usual anti-diabetic diet and did well though he grew very drowsy on several occasions and at one time seemed likely to die. After a while levulose was allowed him and he did well on it, the sugar in the urine not increasing. On admission it was noted that the retinal arteries and veins both appeared to have in them blood of a pale salmon color. The retina was pale. As the patient improved the color in both sets of vessels became more healthy and was quite natural after he had been in for two months. Examination of the blood showed a milky appearance and the serum after clotting was milky. The microscope showed many fine granules, but no globules or anything staining with osmic acid. The author refers to several previously reported cases.

**Some Observations and Comparisons on the Dietetic and Drug Treatment in Chronic Pulmonary Tuberculosis.**—D. Lloyd Smith gives a series of tables showing comparative results following (1) creosote, cod-liver oil, and malt in nine cases; (2) guaiacol in pill form with oil and malt in six; (3) arsenic only in six; (4) nux vomica, gentian and acid, in eight; (5) urea in six, and then gives the uranalysis results in groups 1, 2, and 6. He concludes by saying that diet is of as paramount importance as any of the active principles of any mixture or drug. Meat must be given freely, but the amount for a given case can be determined only by observation. With an abundant mixed diet, cod-liver oil is not necessary. A gain in weight is not everything, as this sometimes happens coincidently with a progressive lung lesion. In such cases the selection of the proper diet is a matter calling for careful observation and selection. Here comes in one great element of success in sanatorium treatment, viz., "the ability to interpret the individual variations in metabolism."

**Cases of Stokes-Adams Disease. (?)**—I. Crawford reports two cases. The first was that of a woman with delayed resolution in pneumonia. He was suddenly summoned to her as she was supposed to be dying. He found her pulseless at the wrists and unconscious, while her breathing was imperceptible. There was a faint, slow flicker to be detected with difficulty in the region of the cardiac apex. Injections of strychnine and digitalin were employed and heat was applied to the extremities and præcordia. She slowly revived, the heart-beats gaining in strength and rhythm until the heart behaved in its customary manner. On inquiry her friends said that the oncoming of unconsciousness was gradual. She had five similar attacks, there being an interval of several days prior to the last, which proved fatal. Digitalis was given, and curiously enough it was stopped about a couple of days before the last attack. Whether that contributed to the fatal result it is hard to say. In the intervals the heart was normal, no murmur or irregularity being observable. There was no history of any previous similar attacks. A similar case was that of a primipara delivered with instruments under chloroform. There was some hemorrhage, but not enough to be dignified by the name of postpartum hemorrhage. She then for no obvious cause passed gradually into a state of unconsciousness. Her pulse became slower and weaker, and finally could not be felt at the wrists; her breathing could not be perceived; her cheeks became white; her limbs grew cold; and the fingers could not detect any sign of life at the cardiac apex. She lay in bed as motionless as if she were carved out of marble. Similar steps toward restoration were taken as in the previous case without result, but the patient rallied inside of twelve hours and made a good recovery.

*British Medical Journal, October* 10, 1903.

**On the Protective Effect Achieved by Antityphoid Inoculation as Exhibited in Two New Statistical Reports.**—A. E. Wright presents two tables showing the incidence of and death rate from typhoid fever in the British Army in India during the year 1901, and the incidence of the fever in Lord Methuen's column at the Modder river, South Africa, from December, 1899, to March, 1900. From the first table it is learned that antityphoid inoculation diminished the incidence rate of tyhoid fever by one-half and the death rate by five-sixths. Statistics suggest that the protective effect of inoculation continues for a minimum of three years. The second table testifies to a diminution of the incidence rate by more than half during the period of observation. It would seem legitimate, in view of statistics set forth above and of previous statistics to infer the continuance of a similarly diminished rate of incidence during the whole of these men's service in South Africa.

**Traumatic Late Apoplexy.**—H. Kron reports a case which shows that a traumatism of the head may subsequently give rise to a cerebral hemorrhage and death therefrom. The patient was healthy before the traumatism and recovered fairly well from the immediate effects of the same. Seven weeks thereafter he was seized with a sudden apoplectic attack and died therefrom. The autopsy showed a large hemorrhage in the right hemisphere, but a normal condition otherwise throughout the body, except a slight cloudy swelling of the renal epithelium and fatty changes in the pericardium covering the right ventricle. Neither of the latter changes are in any way sufficient to account for the apoplectic attack, and and this must be ascribed to the traumatism received.

**Immunization against Tuberculosis.**—F. Neufeld, starting from Koch's view of the non-identity of human and bovine tuberculosis, shows that certain animals (goats, asses, and cows), which are immune to the former but susceptible to the latter, may be immunized thereto by injections with human tubercle bacilli. These animals were given successive subcutaneous and intravenous injections with dead human tubercle bacilli in increasing doses. After a time it was found that they were absolutely immune to infection with the bovine tubercle bacillus. These results in no way contradict those obtained by Koch, who has submitted tuberculous men to injections with dead human tubercle bacilli. For, in the first instance, the process was acute, and in the latter chronic, and in addition the animals employed were healthy when the experiments were begun, while, as before said, Koch has dealt with individuals in which there was already present a tuberculous infection.

**Dependence of Cyclic Albuminuria upon the Circulation.**—Paul Edel thinks that in cyclic albuminuria the periodical appearance of albumin in the urine is due to lowered paterial blood-pressure. Observation shows that in cases of this character the albumin is present or increases in the urine during periods of lowered blood-pressure, but when the arterial pressure is high the albumin is either very much reduced or entirely absent. These facts were obtained by examining patients with cyclic albuminuria previous, during, and subsequent to cold bathing and exercise. In such, during the exercise or bathing, the blood-pressure is high, and no albumin is present in the urine, while following the exercise the reverse holds true. By following out a system of breathing exercises following the exercise, the blood-pressure may be prevented from lowering with the result that no albumin appears in the urine. In healthy individuals following bathing and exercise no considerable period of lowered blood-pressure occurs. In those suffering from cyclic albuminuria, however, the heart, under these conditions, does not seem to be able to answer the demands with the results above noted.

*Deutsche medicinische Wochenschrift, September* 24, 1903.

**Negri's Organism of Rabies.**—Schüder denies the specificity of Negri's protozoa. According to Negri, the diameter of his organism varies from 1 to 15 μ. Shüder has constructed a filter through which the vibrio of cholera cannot pass, but which easily transmits the virus of rabies. Consequently, the organism of the latter must possess a smaller diameter than the vibrio of the former, which, in the average, is .4 μ. Hence the contention of Negri is erroneous.

**Recovery from Progressive Total Bone Atrophy.**—Edm. Rose shows that this result may be obtained by the substitution of a stick of ivory for the atrophied bone. The case reported was of sixteen years' standing—the tibia being the bone involved—and was accompanied in the beginning by suppuration. Nevertheless, the ivory stick enabled the patient to walk during this period, remained healed in the wound for the entire time, and at the end thereof the entire tibia had been practically regenerated.

*Berliner klinische Wochenschrift, September* 28, 1903.

**Work Houses for Syphilitics.**—Edmund Saalfeld recommends the establishment of work houses as a valuable measure in the prophylaxis and treatment of syphilis. In such institutions the work done by the patients could be carefully regulated and controlled so that the spread of the disease through their handiwork would be a practical impossibility. In this manner such syphilitics as were able to work could be improved in their social and mental condition, and when ready for discharge would not be found in the demoralized state that a similar time spent without work in a hospital would bring about. Furthermore, the general results of treatment would be much better than those now obtained in the vast majority of syphilitics treated in clinics, etc., since, if confined in an institution, they would be under constant medical attendance and the treatment could be pursued uninterruptedly until a cure is obtained. Although this idea is a new one and may present many difficulties, its practicability is shown by the success of similar institutions which have been established during the last few years for those suffering from various nervous diseases.

**Alopecia and the Localization of Skin Diseases.**—A. Busche gives the results of his recent experiments with respect to the mode of action of the acetate of thallium in the production of alopecia, a fact which was recorded by him in December, 1902. As stated at that time, if minute quantities of this substance are administered to white mice there develops, after a short period, an alopecia which is occasionally diffuse but usually circumscribed and limited in location to the head and face. Bettmann has confirmed the same as occurring under similar conditions in rabbits, and in the present experiments these animals were exclusively employed. The results are negative rather than positive, and the mode of action of thallium in producing the condition has not been determined. Nevertheless, several interesting facts have been established with respect thereto. The production of alopecia under similar conditions is not peculiar to thallium, as the author formerly held, since other substances, notably mercurial and lead salts, give rise to a falling out of the hair. The mode of action, however, of these various substances cannot be identical, as the character and localization of the alopecia differs according to the substance used. Nor is it similar to the loss of hair which is so commonly observed during convalescence from many infectious diseases, and which is undoubtedly due to a general reduction in the vitality of the organism. The general characteristics of the latter are entirely different from the alopecia due to thallium. As is well known, this substance has a decided action in reducing the activity of the sweat glands. The alopecia, however, cannot be due to this property, since it regularly occurs when the action upon the sweat glands is nullified by the simultaneous administration of pilocarpine or physostigma with the thallium. That the action of the thallium in this respect is exerted through the production of pathological changes in the nervous system is extremely unlikely, as the entire clinical picture produced by the administration of thallium in minute doses denotes merely a functional disturbance of the nervous system. The localization of the alopecia due to thallium appears to be definite, since it never appears upon other regions of the body, although various measures were employed to reduce the resistency of the hair follicles in such locations.

*Münchener medicinische Wochenschrift, September* 29, 1903.

**Plastic Quadriceps-operations.**—Sigmund Stiassny reports an operation upon a cat, in which he divided the quadriceps and united to the divided tendon the end of the adductor magnus which he had dissected from its insertion. Primary union was obtained and the action of the quadriceps fully restored.

**Removal of Gallstones by Irrigation.**—Franz Kuhn recommends this method. The bile passages are to be washed out with a normal salt or similar solution by the means of a water-tight tube introduced through the fistula, if one exists, or at the time of the operation. In addition to removing stones or other obstructions, the irrigations have a favorable influence upon the mucous membrane which lines the biliary passages. The pressure of the fluid depends upon the height of the column from which the stream flows. This should usually not exceed 50 cm., but may occasionally be increased to 150 cm. The velocity of the stream depends upon the obstruction or non-obstruction of the bile ducts. Under normal conditions the velocity is 25 c.c. in one-half a minute with a water column of 50 cm. No unfavorable symptoms are observed as the result of the irrigations, except that when the pressure is too high attacks simulating biliary colic are produced. Such attacks may be produced at will by increasing the pressure of the fluid, and they show conclusively that biliary colic is caused by an increased pressure of the bile in the biliary passages, due to some obstruction in the same.

*French and Italian Journals.*

**Antiseptic Washing of the Intestines.**—A. Gauducheau carried out a series of experiments on dogs with a view of ascertaining whether the dangers attending the injection of poisonous antiseptics might not be avoided or modified by the simultaneous use of hypodermoclysis and purgation. Mercury was administered, while three physiological processes were initiated: (1) Preliminary repletion of the circulatory system by means of a subcutaneous injection of a large amount of fluid to cause vascular hypertension in general and of the intestinal blood vessels in especial. This induces a certain amount of resistance to absorption. (2) Elimination of the poison through the kidneys. This also is accomplished by means of the hypodermoclysis. (3) Purgation by means of sodium sulphate, which increases peristalsis and assists exosmosis. The author is gratified with the results of his experiments, and intends to pursue his researches.—*Gazette Hebdomadaire des Sciences Médicales*, August 30, 1903.

**Adrenalin in the Treatment of Purpura Hæmorrhagica.**—M. Loeper and O. Crouzon report a case of grave purpura which would not yield to treatment by ergotin, serum, calcium chloride, and the sulphate of quinine. Even adrenalin applied to the gums was of no avail in checking the local hemorrhage, but in twenty-four hours there was marked improvement, and in five days a complete cure of the condition, thanks to the ingestion of 4½ milligrams of adrenalin. Up to the present time adrenalin (or renalin, the action of which appears to be the same) has been administered by local application for nasal, laryngeal, and ocular hemorrhages, subcutaneously or by intrapulmonary injections in hæmoptysis, and by washings and ingestion in gastric and intestinal hemorrhages. The authors are aware of one only case in which a cure is reported in Werlhoff's disease after daily injections of one milligram of adrenalin. In their case they tried the effect of absorption through the digestive tract with excellent results, as shown above.—*Le Bulletin Médical*, September 2, 1903.

**A New Method of Administering Boric Acid in the Treatment of Tuberculosis.**—A. F. Plieque considers that Gaucher proved the efficacy of boric acid in the relief of many symptoms of tuberculosis, and in an improvement of the general condition. Given by the mouth, however, the amount necessary to produce the desired results caused serious digestive disturbances. The author has found that given in a rectal injection (4 grams of boric acid in about 125 grams of fluid) tolerance is perfect. The acid may be dissolved in a teaspoonful of boiling water, and then added to milk, which is injected. Patients who are unable to take the medicament by the mouth support it well when given in this way, and show improvement in the temperature curve and in the expectoration, although the number and virulence of the bacilli are not sensibly affected. Elimination by the urine is more marked than by the sputum. This form of treatment would seem to be applicable to tuberculosis of the kidney; Gauchard used it successfully in combating hæmaturia and pyorrhœa. It should be of equal value in pyelitis and cystitis.—*Le Bulletin Médical*, August 29, 1903.

**Latent Scarlatina.**—P. Caziot reports cases of latent or walking scarlitina, of which there are two types, the first eruptive, with a slight general eruption, and slight tracheopharyngeal irritation, with some headache; the second characterized by angina and pharyngeal redness, a little fever and slight asthenia. No eruption has been observed, but it may exist. This is merely an attenuated form of scarlatina, and not of great importance, except from the point of view of possible contagion.—*Revue Française de Médecine et de Chirurgie*, September 28, 1903.

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

*Proceedings of the Sixteenth Annual Meeting, Held in Chicago, Ill., September 22, 23, and 24, 1903.*

THE association met in the Northwestern University Medical School, under the presidency of Dr. L. H. Dunning of Indianapolis, Ind.

Dr. WILLIAM A. EVANS of Chicago delivered an address of welcome on behalf of the local medical profession, which was responded to by President Dunning.

After a short executive session, the reading of papers was proceeded with.

**The Relation of the Colon to Abdominal Tumors.**—A paper with this title was read by Dr. JAMES F. BALDWIN of Columbus, Ohio. The colon, while it was quite movable, had its mesocolon well fixed to the abdominal parietes. By inflating the colon, when necessary, by pumping air in at the anus, its relationship to abdominal tumors could be quite definitely determined, and this relationship would enable an accurate diagnosis of the tumor to be made in many cases in which such diagnosis would otherwise be impossible. This was particularly true in differentiatng tumors of the spleen, pancreas, kidneys, liver, including the gall-bladder, etc., from tumors originating in the pelvis or in connection with the small intestine and mesentery.

**The Value of Vaginal Cæsarean Section, with Report of Two Cases.**—Dr. M. STAMM of Fremont, Ohio, read a paper on this subject. He stated that to Duhrssen of Berlin the credit was due for having introduced this valuable method into practice. The clinical reports of operations undertaken on various indications spoke favorably of this method. The indications for this operation, as given by Duhrssen, were: "(1) Abnormal conditions of the cervix and lower segment of the uterus (carcinoma, myoma, rigidity, stenosis, partial pouch-like distension of the lower uterine portion). (2) Dangerous conditions of the mother which may be removed or relieved by prompt emptying of the uterus affections of the heart, lungs and kidneys. (3) Conditions of the mother where death is imminent and can be foreseen." The last two indications had value only in cases in which the cervix was closed and not dilatable, or in which the depressing influence of labor pains should be obviated, as in affections of the heart and lungs. In pregnancy complicated with cancer of the uterus, Duhrssen advocated immediate vaginal section, with subsequent extirpation of the uterus, no matter at what time of pregnancy or at what stage of labor this condition was encountered. Duhrssen's mode of procedure was described by the author.

**The Limitations of Cæsarean Section.**—In a paper on this subject, Dr. E. GUSTAV ZINKE of Cincinnati, Ohio, stated that the basis of his paper was an analysis of eighty-eight cæsarean sections, including eight Porro operations, which had been reported by fifty-two different authors since January, 1900. The causes for which the operation was performed were, in the order of their frequency, as follows: For pelvic deformity, 28 times, namely, flat rachitic pelvis, 13; uniformly contracted and rachitic pelvis, 7; irregularly contracted, rachitic pelvis, 4; flat rachitic pelvis, complicated by eclampsia 3; flat rachitic pelvis, complicated by tumor, 1. For justominor or uniformly contracted pelvis, 12 times; for fibroid tumors obstructing labor, 11 times; for eclampsia, 6 times; for hysteropexy, 6 times; for cicatricial contractions of vagina, 5 times; for causes not stated. 4 times; for simple disproportion between fetal head and pelvis, and lack of expulsive power, 3 times; for carcinoma of cervix, 3 times; for carcinoma of rectum, 2 times; for placenta prævia, 2 times; for retrodisplacement, impaction, and adhesion of fundus, 2 times; for gunshot passing through gravid uterus, 1 time; for ovarian tumor obstructing labor, 1 time; for threatened rupture of uterus, 1 time; for congenital displacement of kidney, 1 time. Among the 13 cases of flat rachitic pelvis was Coakley's case, in which the operation was done three times in six and a half years, and Ill's case, in which the operation was done twice in one year. Of these 88 cases, 66 mothers and 56 children lived. In 7 instances, however, it was not stated whether the mother lived or died, and in 13 the same information was wanting as to the child. In the consideration of the maternal and fetal mortality, the cases in which there was no reference as to the result of the mother and child were excluded. Thus it was found that out of 81 mothers, 66 lived—81.5 per cent Again, it was found that death in 5 of the mothers was really due to malignant disease, and the patients recovered from the effects of the operation, death taking place two months, four months, one year, and two years, respectively, after the operation. Counting these five cases as recoveries, 71, not 66, mothers lived. Maternal mortality, 12.34 per cent. Of the 90 children born, 56 lived. If the 13 cases were excluded in which the result as to the child was not stated, the fetal mortality amounted to 49 per cent. But a careful study of all cases revealed the fact that 3 of the children were dead before the operation; 2 succumbed during the operation; 7 died within twenty-four hours; 4 within forty-eight hours. Three lived two weeks, and one died of enteritis at the end of three months. If there were added to the list of children surviving the operation those who lived twenty-four hours and over, 15 in all, the immediate fetal mortality was reduced to 25.26 per cent. The principal object of the paper was to determine as accurately as possible the limits of the sphere of usefulness of cæsarean section in the light of recent advances in operative obstetrics and for the sole purpose of obtaining the best results for both mother and child under the most trying circumstances.

**The Gilliam Operation: A Clinical Contribution.**—Dr. EDWARD J. ILL of Newark, N. J., followed with a paper on this subject. The author had done Gilliam's operation eighty-six times since the author described it three years ago. In other words, he had done it in 68 per cent. of all cases operated on for retrodisplacements. There were no deaths. Fifty-one of these cases had reported themselves as entirely well, six as markedly improved, and four as no better. Seven had become pregnant, and two had given birth to children normally. Only one of the four reported as no better had a relapse of the malposition. This one was operated on again and an atrophy of the distal end of the round ligament discovered. The writer had modified Dr. Gilliam's operation by not piercing the whole abdominal wall, fearing a weakness from which hernia might result. He would separate the rectus abdominis from its anterior sheath and pierce the rectus muscle, the inner sheath, and the perineum, and progress, as taught by Dr. Gilliam, fastening, however, the round ligament to the posterior surface of the anterior sheath of the rectus muscle with chromicized catgut, thus leaving a strong fascia intact.

**Analysis of Common Causes of Death Following Pelvic and Abdominal Operations.**—In a paper on this subject, Dr. JOSEPH PRICE of Philadelphia, said that he had selected this topic not because he had had a high mortality, but for the reason that it was one of great interest to the members. He said he had written several papers on postoperative complications and several upon repeated operations in incomplete abdominal procedures. This was the class of cases that perplexed him more and more as he grew older, and gave him the only mortality he met with nowadays. Recently he had had a number of trying and sad experiences. In one case a patient came from a prominent hospital after a very simple but incomplete operation, in which the operator had only partially removed one pathological ovary and tube, leaving the

organs on the other side in a badly diseased state. She was sent to him some four months following this incomplete procedure, emaciated, septic, and suffering acutely. He opened the abdomen and found a strongly adherent bowel and omentum. The consolidation of everything made him strongly suspicious of what he would find below. The viscera freed, he found a huge four-foot gauze towel anterior to the uterus, the towel and pus pushing the uterus well back. The stench contaminated the hospital in a few seconds. This patient lived but a few hours, her death being the only one in the hospital in a long series, greatly distressing the operator, nurses, and all concerned. Postoperative sequelæ and deaths from gauze were very common. He was satisfied that they were thrice more common than from sponges. For a number of years he used sponges, and valued them for clean work, for packing, or for a dry operation, and he believed viscera troubled him less than at the present time. He was then wholly ignorant of postoperative sepsis in his own work, and in that of his pupils. Had he now the time to take care of his sponges, he would go back to them, as highly as he valued gauze. To his mind it was one of the most valuable materials in surgery. He spoke of the value of good nursing in the reduction of mortality rate. A number of good operators attributed their low mortality wholly to the use of gloves. One very scientific teacher asked him before adopting the use of gloves, if he did not think 12 to 15 per cent. was a low mortality, taking the cases as they came? He replied, "No, too high." After adopting the gloves he reduced his death rate to about *nil*, but his precautions, said Dr. Price, were all redoubled. For example: After operating on a septic case, other operations were postponed for thirty-six to forty-eight hours. Again, in a study of the complications and pathology, in his reported cases, Dr. Price failed to find one which could have died from good surgery. Recently a brilliant young surgeon assisted him in an operation for acute gangrenous and perforative appendicitis, complicated with general septic peritonitis, the peritoneum being bathed in septic fluid. This patient got a wash toilet and a coffer-dam drain; she never had a bad symptom. The young surgeon remarked that nearly all these cases ended fatally in his hands. In a splendidly appointed hospital, with which this young surgeon was connected, the mortality was high in appendicitis operations. His reasons for alluding so fully to this subject were that the disease was so common and the death rate so high. Vaginal incisions and perforations favored a high mortality in later operations, made for the clean removal of the remaining pelvic pathology. Puriform tubes and ovaries, suppurating tubes and ectopic pregnancy, seldom allowed sufficient improvement in vital force and stamina to bear well the complete operation—suprapubic—after they had been incised through the vagina. Primarily they would all have been easy by complete methods and without mortality. The choice of method and material was of paramount importance to good work, and the suprapubic procedures, when complete and done early, drainage being used when necessary, should, like the infrapubic, when done by one of the finished operators, give a mortality close to *nil*. He had done a large number of vaginal hysterectomies for malignancy of the uterus, cervix or fundus, and for small fibroids, without a death, and it was one of the easiest operations he was asked to do. In suppurative forms of tubal and ovarian disease he did not consider the vaginal route complete surgery, because the adherent omental and bowel adhesions and the diseased appendix were wholly neglected.

**Report of a Fourth Consecutive Successful Operation for Acute Perforated Gastric Ulcer, with General Infection of the Peritoneal Cavity.**—Dr. H. HOWITT of Guelph, Ont., presented a paper on this subject. Acute gastric ulcer perforation, as understood by him, referred to those cases in which nature failed to prevent the escape of gas, liquid, or other contents of the stomach by adhesion of the part to adjacent structures. In reference to successful treatment, attention was called to the importance of early diagnosis and prompt action on the part of the surgeon. He believed that the diagnosis should be made without difficulty when the perforation occurred in a young, anæmic girl, who had a previous history which indicated the presence of an ulcer, and that it should not be difficult in the majority of the other cases, for there was generally a history of after-meals gastric distress, and frequently other symptoms to indicate the trouble. With or without such previous history, the sudden onset of intense pain in the epigastric region, the pronounced shock, the rigidity of the abdominal wall and the thoracic character of the respiratory movements aided in arriving at a correct conclusion; and, if in addition to these the initial pain radiated in a certain direction, and the position of greatest suffering changed and gradually took a downward course in the abdomen, the diagnosis might be made without delay. In the rare instances of rupture of the gall-bladder or perforation of the duodenum in which the symptoms closely resembled those of gastric perforation, the indications for prompt surgical treatment were practically the same. In perforation of the anterior wall to the left of the median line, the material, and consequently the pain, followed a course along the inner side of the descending colon. In all other situations along the descending colon toward the pelvis. The administration of morphine in the early stage, before a diagnosis had been made, often prevented timely recognition and prompt action. It was the general practitioner who was first called, and until he became more familiar with the true import of the initial symptoms successful operations would not be common. The speaker believed that the symptoms indicated the position of the ulcer in the stomach in a manner sufficiently definite for all practical requirements of the surgeon. Before perforation took place, when the ulcer approached the peritoneal coat, a local sensitive area of peritonitis was produced, and it was very sensitive to pressure or other form of irritation. Hence the posture of the patient was that which avoided pressure and kept the contents of the stomach away from the ulcer. For instance, when the ulcer was on the anterior wall, the patient was more comfortable when lying on the back, and so on, according to the position of it. When it was on the anterior wall, point pressure of a superficial character might, by causing severe pain, indicate the exact position. Whether caused by pressure, food or otherwise, the pain, when severe, tended to radiate in certain directions, according to the position of the ulcer. Thus, if near the pylorus and on the anterior wall, to the right, or to the right and downward. On other parts of the anterior wall, to the left and to left and upward to shoulder. On posterior wall, to back immediately behind its situation and to right or left, according to whether it was right or left of spinal column, and upward to interscapular space. In acute perforation of the stomach wall with distension of the bowels, the organ was collapsed and crowded on to the ribs and diaphragm in such a manner as to render it impossible for any surgeon to deal with the trouble without exposing more or less of the intestines. A large incision, collapse of the distending coils of intestines by temporary enterotomy and evisceration rendered the work easy and more expeditious, and with less damage to the delicate parts than was possible by any other method. When the perforation was large, drains were used in each flank, and in the pelvis, not through a large incision, but through separate stabs.

**Should the Uterus and Ovaries Be Removed in Operating for Double Pyosalpinx?**—Dr. C. C. FREDERICK of Buffalo, N. Y., read a paper on this subject. The operation, at first practised by Tait and his followers for several years, consisted in removing both the tube and ovary through the suprapubic incision, leaving the uterus.

In making a pedicle common to both tube and ovary, there was of necessity an incomplete removal of the tube, leaving, in most cases, a part of the proximal end. Many patients were cured and others were not cured, the failure being, in many instances, due to a continuance of the diseased process in that part of the tube remaining. Some of them who had undergone this incomplete operation were again operated upon; the uterus was removed, and in many cases a cure resulted. The natural inference was that the uterus was the offending organ which prevented cure after the first operation; hence arose the teaching that the uterus should be removed with the diseased tubes, in order to insure success. Then came the resort of the French school to vaginal operation for pus tubes, and then every vestige of uterus, tube, and ovary was removed, whether it was necessary or not. After an experience of about fifteen years with the various surgical procedures, and noting the effects of these operations, gynecologists were in a position to decide quite accurately the amount of pain, discomfort, and illness due to disease of the various anatomical parts of the woman's sexual apparatus. As a result of these observations and deductions, it was not necessary to sacrifice all of these organs when they were not all hopelessly diseased. In other words, gynecologists were justified in removing nothing but those organs which were distinctly diseased, and they were in duty bound to retain for the woman all that were not diseased. The rule should be to save as much healthy ovarian tissue as possible, even if it be only the fourth or eighth part of one ovary. In some rare instances the uterus should be removed. If the condition was known to be tuberculous, the uterus should certainly be removed. But even if both tubes and uterus were taken out, one should still preserve all the ovarian tissue possible.

**The Indications and Technique of Vaginal Drainage for Suppuration in the Pelvis.**—Dr. ALBERT GOLDSPOHN of Chicago discussed the chief routes by which infection entered the female pelvis. He described the type of pathological changes resulting from each route. While pelvic cellulitis was rare and of little significance in non-puerperal infections, via the tubes, it was the leading or primary anatomical change in puerperal infections, via the lymphatics. When vaginal evacuation of the pus in pelvic suppuration needed to be followed by a more radical secondary operation, in many cases it enabled the inflammation in the associated uterus or tubes, or ovaries, to subside during the interval, so that they need not be removed, as would have been deemed necessary if a radical operation had been performed in the first instance or during the acute stage. Vaginal drainage helped to save life in cases that had become too feeble for a radical procedure to be applied at once. Preliminary drainage improved their condition so that they could stand a radical operation later, with no higher rate of mortality than obtained after abdominal section in other cases that were not so reduced. This operation should never be a puncture with a trocar, knife or scissors, but should always be a transverse incision into the posterior cul-de-sac, preferably with the thermocautery. From this entrance, as a vestibule, laterally located purulent accumulations, if not yet opened were best attacked by a finger assisted by a forceps.

**Shortening of the Round Ligaments by the Blunt Hook Method.**—Dr. H. W. LONGYEAR of Detroit, Mich., described this method of shortening the round ligaments as follows: "The location of the internal ring is determined by finding the point of crossing of Poupart's ligament and femoral artery, as the ring is situated immediately back and above it. Beginning half an inch inside this point and cutting toward the pubic end parallel to Poupart's ligament, a one-inch incision is made through skin, fat, and superficial fascia. Eye retractors and blunt hooks are then used, the tissues separated down to the aponeurosis of the external oblique, which is thus laid bare to the eye, to the extent of about one square inch. A puncture is now made through this aponeurosis one-quarter of an inch long, situated just above Poupart's ligament and to the back of the square inch of cleared aponeurosis, and through this the blunt hook is inserted and the ligament drawn out, usually with more or less of the fat of the canal along with it. The ligament is isolated and its fibrous attachments stripped back toward the internal ring with blunt pointed dressing forceps, the ligament drawn out to the necessary length, an aneurysm needle passed through the aponeurosis and the loop of ligament drawn through this, folded back on itself, and, with one stitch of kangaroo tendon, made fast, the suture embracing in its grasp the edges of the aponeurosis where the ligament first passes through it, half of the ligament at the same point, and half on each side of the loop that is folded back on it. The skin is then closed by a running catgut suture, and dressings applied. The operation is applicable only to cases of mobile uteri without diseased appendages, in which cases it is an ideal procedure, or to cases in which adhesions may have been previously broken up by abdominal section. A number of devices have been resorted to for the purpose of catching the ligaments and suturing them through the abdominal incision, and thus avoiding the making of the secondary operations in the groins, but they cannot expect to equal the method which leaves the shortened ligament in exactly its normal position."

**The Need for Study of the Symptoms of Perforation in Typhoid Fever, and the Life-saving Possibilities of Early Operation.**—In a paper on this subject, Dr. W. D. HAGGARD of Nashville, Tenn., stated that only about three hundred cases of operation for intestinal perforation in typhoid fever had been reported since the first case in 1884. Granting that this represented only one-half or one-fourth, the number was pitifully meager when it was computed that 25,000 persons died yearly in the United States from perforation and peritonitis in typhoid fever. He made a plea for an early diagnosis and an attempt, at least, to save a part of this appalling number. On a basis of a possible 30 per cent. recovery, which was shown to have been attained in the reported cases, 7,500 lives might be preserved yearly by prompt operation The difficulty lay in making an early diagnosis. The abdomen of typhoid cases should be exposed and carefully examined daily. No abdominal symptom or sign should be considered trivial. Pain was usually the first note of alarm—sudden, severe, colicky, and persistent. Collapse at the time of perforation occurred in only 6 or 7 per cent. Fall in temperature, while not constant, was significant; but prompt rise in pulse was uniform and a symptom of the highest value. Tenderness, rigidity, and localization of pain commonly occurred in the order named. Continuance of pain would distinguish it from colic. Exploratory laparotomy, under cocaine, if necessary, was earnestly urged as a diagnostic measure in suspicious, but doubtful, cases. A plea was made for recognition and interference with the early and mild symptoms, and the classical picture of perforation so-called; the drawn features; cold extremities; feeble pulse; sighing respiration; distended abdomen; restlessness and delirium were not symptoms of perforation *per se*, but of the consecutive peritonitis and really of impending death. A man in the second or third week of a mild attack of typhoid fever without previous abdominal symptoms, and progressing without incidence, who was suddenly seized with acute, paroxysmal, colicky pain in the right iliac region, that caused him to cry out, that did not subside or was not relieved by the ordinary measures, followed by a drop in temperature and a sudden rise in the pulse, and heightened temperature, succeeded by sensitiveness and right-sided rigidity, and a rapidly increasing leucocytosis, might be said to have perforation, not absolutely but with sufficient assurance to demand immediate exploration. It was admitted that all cases did not present the typical symptom-grouping, and an analysis of the value of the

various symptoms was detailed. Statistics of all the reported cases were presented as regards the greater frequency in men, the rarity in children, the predilection of occurrence in the second and third weeks, the preponderance of location in the ileum; the likelihood of finding the perforation single (84 per cent.); the relative locations in the various portions of the canal, and the uniformity of death without operation. The surgeon should stand in close relationship with the physician in all typhoid cases, as was done in appendicitis. Doubtful cases should have the closest surveillance and operation at the first indication of a beginning peritonitis. Dr. Haggard reported three consecutive successful operations for intestinal perforation, two of which were localized; one with abscess; one with localized peritonitis, simulating appendicitis, with three perforations, and one operated on eight and a half hours after the onset of pain, on the twelfth day of a mild attack. Operation was performed at night in a farmhouse by lamplight. The technique was described, and statistics presented showing a recovery rate of 36 per cent. in cases of perforation before the advent of peritonitis; of 47.3 per cent. in cases of localized peritonitis, and 21 per cent. in cases of generalized peritonitis. An earnest advocacy was made for a realization of the possibilities of life-saving in this hopeless class of sufferers.

(To be continued.)

## NEW YORK STATE MEDICAL ASSOCIATION.

*Twentieth Annual Meeting Held in New York City, October 19-22, 1903.*

*Monday, October 19—First Day.*

**Meeting of Council and Fellows.**—The meeting of the governing body of the association convened in the New York Academy of Medicine at 1.45 P.M., at the call of the President, Dr. Frederick Holme Wiggin. In his address on the condition of the association, and its needs, the President stated that during the past year fourteen new component societies, or county organizations, had been added, making a total of thirty-five such societies now in the State association. During the same period 372 persons have been added to the active membership and 60 have been reinstated, while 23 have died, 15 have resigned, and 2 have removed out of the State. This gives a total membership of 1,757, and entitles the association to send four delegates to the American Medical Association. The President was of the opinion that the increase in membership was chiefly attributable to the inauguration of the system of defending the members in suits for alleged malpractice. It was suggested that the ratio of representation from the county associations should be 1 to 100, instead of 1 to 10, each county association being allowed at least one representative. It was also recommended that the initiation fee be restored, and that the collection of all dues be made by the State treasurer. The President also recommended that the committee on legislation should take steps to secure the passage of a law requiring those bringing suits for malpractice against physicians shall be bonded in evidence of good faith.

**Officers Elected.**—*President*, Dr. William H. Thornton of Buffalo; *Vice-President*, Dr. Charles S. Payne of Liberty; *Secretary*, Dr. Guy Davenport Lombard of New York; *Treasurer*, Dr. Frederick A. Baldwin of New York.

*Tuesday, October 20—Second Day.*

**Sea Bathing.**—Dr. R. ABRAHAMS of New York read a paper on this subject. He had found sea bathing particularly useful in pityriasis versicolor, chronic eczema and senile pruritus, whereas the same affections when treated by means of salt water in bathing establishments. The author suggested the following reasons for this difference: (1) The longer immersion in the sea; (2) the pounding action of the waves; (3) the exposure to the sun and the concentration of the water upon the cutaneous surface between the dips in the sea, and (4) the salutary effect upon the skin of rolling in the sand on the beach.

**Treatment of Compound Fractures.**—Dr. V. D. BOZOVSKY of Dunkirk read this paper. He said that if the wounds of the soft parts were in or near an infected region, it should be enlarged and drained. Rise of temperature and a dry, brown tongue pointed strongly to infection. Silver wire was the best material for suturing the bones; the next best was silkworm gut. Large fragments without periosteum would not unite, but small chips would do so, even when taken out, cleansed, and replaced.

**Stab Wounds of the Abdomen.**—Dr. F. J. DOUGLAS of Utica presented this paper. He said that no other class of cases had a more unreliable symptomatology than this. It was well not to rely upon any one symptom. As a rule, there would be quickening of the pulse, rapid and shallow breathing and an anxious countenance. The real conditions could be determined only by an exploratory laparotomy, and this should be done even in the presence of shock. Probing was unsatisfactory and dangerous, and could not be too strongly condemned. The omentum and gut should be carefully inspected, and any foreign matter present removed by irrigation with sterile water. After suturing any wounds of the viscera the peritoneal cavity should be flushed out, and if there were much shock the peritoneal cavity should be left filled with hot salt solution. Ordinarily, drainage was not required. The operation, if properly done, never killed, whereas neglect of its immediate performance often jeopardized life. Three illustrative cases were reported.

**The Relation of the Municipal Milk Supply to the Health of Children.**—Dr. GEORGE W. GOLER of Rochester was the author of this paper. He said the figures to be cited in the paper included every death under five years of age from any cause. From 1891 to 1896 there were 2,879 deaths under one year, and 1,496 under five years of age. From 1897 to 1902, inclusive, *i. e.* during the period when special care had been taken to improve the milk supply, there were 1,887 deaths under one year, and 876 deaths between one and five years of age. This diminution of mortality for the last period was 65 per cent. for children under one year, and 58 per cent. for children between one and five years of age. In the first period more than 28 per cent. of children died under five years of age; in the last period 19.5 per cent. died. No process of sterilization could clean milk after it had once become dirty. There should be a bacterial standard of cleanliness adhered to in order that the milkman might secure a license. An attempt had been made in the city of Rochester to maintain a standard of 100,000 bacteria per cubic centimeter for the past four years. At the beginning, 27 per cent. of the samples gave an average of 837,000 bacteria to the cubic centimeter. After the bacterial standard already mentioned had been established, 391 samples gave an average of 796,000 bacteria to the cubic centimeter, but 15 per cent. of the samples still contained over five million bacteria to the cubic centimeter. In 1901, 287 samples averaged 275,000 bacteria to the cubic centimeter, and 9 per cent. gave over five million. In 1902, 531 samples averaged 215,000 bacteria per cubic centimeter, 74 per cent. of the samples coming within the prescribed standard, and 6 per cent. still showed more than five million bacteria. So far, in the present year, 329 samples gave an average of 209,000 bacteria, 33 per cent. came within the standard, and 4 per cent. showed more than five million bacteria present to the cubic centimeter. In the summer of 1897 the Health Commission had been asked for an expenditure of $400 to provide milk stations for selling milk for nurslings at cost price. At a central station outside of the city the milk was received and prepared. The milk itself was neither sterilized nor pasteurized, but everything coming in contact with the milk was sterilized. Similar precautions were observed at the dairy. Last summer the daily samples of milk examined showed an average of 14,000 per cubic centimeter, while for the same days the ordinary city milk averaged 235,000 per cubic centimeter. Since the establishment of this system, there had been a

steady and decided diminution in the infantile mortality for the city of Rochester. The most important feature of the work was its educational aspect.

Dr. De Lancey Rochester of Buffalo detailed the unsuccessful attempts that had been made in his city to purify the milk supply. Sterilization and pasteurization of milk he characterized as a sop to those who desired to supply dirty milk.

Dr. James J. Walsh of New York remarked that there were 15,000 fewer little graves in Chicago than there would have been if the sanitary condition of that city in 1895 had not been improved

Dr. H. O. Marcy of Boston spoke of the efforts made to improve the milk of Boston, and then described a special process that had been carried on in New Hampshire for the past six years. The milk was taken from healthy cows and quickly transported to the receiving station, where it was refrigerated and made into a kind of sherbet. It was then put into a centrifugal machine and most of the water was driven out very quickly. The milk in this concentrated form did not undergo change nearly so quickly as ordinary milk. Such milk would keep sweet for about two weeks. The possibilities of this process were so great that he expected it would in time revolutionize the distribution of milk. This product was a pure milk from which very little of the albumin and salts had been abstracted.

**The Causes of Failure after Operation for Nephroptosis.**—Dr Augustin H. Goelet of New York presented this paper. The causes of failure, briefly stated, were said to be the following: (1) Delay in operating until the health of the patient had become seriously impaired; (2) delay in operating until the kidney had become greatly disabled, or incurable nephritis had developed; (3) the existence of irreparable ptosis of the abdominal organs as a complication of the nephroptosis; (4) the failure to prepare the patient properly for the operation, and thus avert severe retching and vomiting following the anæsthesia; (5) incomplete detachment of the colon from the kidney; (6) delay in anchoring the kidney by operation until this organ had become permanently attached; (7) penetration of the structure of the kidney by the sutures; (8) attachment of the kidney too low down in a position where it is exposed to irritation by the clothing or corset; (9) too early removal of the sustaining sutures; (10) delay in removing the gauze drain; (11) allowing the patient to turn upon the opposite side too soon; (12) allowing the patient to assume the erect position too soon, *i.e.* before the end of three weeks; (13) the neglect to adjust a proper support for the lax abdominal walls when the patient resumed the erect position; (14) too early resumption of the corset, or its improper adjustment; (15) permitting too soon such exertions as put a severe strain on the freshly attached kidney; and (16) the neglect to correct derangements of the digestive apparatus and other conditions caused originally by the prolapse of the kidney.

Dr. E. D. Ferguson of Troy preferred to decorticate thoroughly the kidney, and then insert a row of sutures from pole to pole, after which the remaining portion of the fatty capsule should be brought back, thus exposing a fresh surface for union.

Dr. Martin B. Tinker of Clifton Springs, said that his observations led him to believe that many failures after nephropexy were really due to an associated general enteroptosis.

Dr. R. H. Gibbons of Scranton, Pa., was of the opinion that the symptoms observed in cases of loose kidney were largely the result of interference, by reflex disturbance, with the functions of the small intestine through irritation of the large intestine.

**Results of Operative Treatment of Cancer of the Rectum.**—Dr. James P. Tuttle of New York read this paper. He said that it was very common to advise persons suffering from cancer of the rectum to have an inguinal colotomy done. The patient was then permitted to drag out a more or less miserable existence, until death closed the scene after an average interval of nine months. He wished, therefore, to present the results up to date obtained by him in forty-three excisions. The proportion of carcinoma of the intestinal tract was gradually increasing; formerly it was about 21 per cent., but more recent statistics had raised this figure to 23. On an average, life was prolonged about nine months after the discovery of the disease whether or not colotomy was done. The operation of excision was an exceedingly difficult procedure, and there was great liability to infection. The speaker asserted that no other method but extirpation had ever cured a single well-authenticated case of carcinoma of the rectum or sigmoid. The average prolongation of life was from six months to three years greater after extirpation than after colostomy. Colostomy was the only method that could be compared with excision. His own opinion was that patients without colostomy would live just as long as with it. Only in scirrhous growths with absolute occlusion of the gut, and in cases of the hemorrhagic type did he believe colostomy was indicated. For relief of pain the operation of extirpation was perfect, and, as regards restoration of strength and usefulness, it exceeded all other methods because it entirely did away with diarrhœa and disturbances of digestion. Recurrence of the disease rarely took place in the original site. The mental effect was not to be despised, for this operation alone could hold out any prospect of an ultimate cure. Of the forty-three cases, twelve were unsuccessful. Of the twenty-nine remaining only twenty-two had been traced and were found still living. Of these sixteen had survived the operation two years or, one of them for eleven years, one for ten, one for nine, one for seven years, and the others for varying periods of two years. The greatest of all the causes of death in this class of cases was a late diagnosis. Three out of the seven cases lost were really from this cause. Every case of diarrhœa, with or without blood, if lasting for over two weeks, required not only a digital, but an instrumental examination of the rectum or colon to decide what was the local condition responsible for this persistence of the affection. If such an examination were not made, and the patient later suffered from carcinoma, the physician could not morally avoid responsibility in the matter. With early diagnosis, the speaker said, he was confident that even the remote results from extirpation would be materially improved. Next to late diagnosis, infection was the chief cause of death. In four of the seven fatal cases the direct cause of death was infection; three patients died from what was generally called shock or exhaustion, but the high temperature that developed shortly before death made him believe that these also were instances of infection. In one case death was due to cutting the sigmoid artery with the production of gangrene of the upper segment of the bowel. With regard to what desperate cases it was justifiable to operate upon, Dr. Tuttle said that ordinarily it was stated that one should not operate if carcinoma of the rectum were not movable, but we should consider also the patient's rights in the premises. Of four such desperate cases, two had been saved, although in each instance he had only operated after repeated solicitation from the patient, and against his better judgment. It was true, by doing these operations he had spoiled his statistics but that was a small matter compared with the saving of these lives. One of these patients appeared to be almost moribund on leaving the operating table, though he survived, and now, after a period of three years and a half was alive and well, and only had to urinate through a fistula in the perineum. One of the cases reported was that of a person who had been operated upon by Dr. C. McBurney and had remained well for ten years, and then had a recurrence. Dr. Tuttle said he operated upon this recurrence, and the patient was again apparently well. The case was cited to show the great importance of keeping all these cases under prolonged observation, no matter whether or not they had gone without recurrence for a

period of four years. Eternal vigilance was the price of success in this field of surgery. Several of the patients were exhibited, and an opportunity was afforded for examining them.

Dr. E. D. FERGUSON suggested the performance of a preliminary or a coincident colostomy in cases in which it was possible to bring down the upper portion of the gut and attach it to the lower segment, the object being to avoid the danger of infection arising from evacuation of the bowel.

**One of the Dangers in the Surgery of the Biliary Passages.**—Dr. E. D. FERGUSON read this paper. He said that experience had taught him that preliminary operations, and especially severe manipulation in the deep biliary passages added greatly to the risk of the operation. His endeavor was to secure a symptomatic cure rather than to do an ideal operation in all cases. It should be an invariable rule to do that operation which would give the least shock. This was usually the establishment of a temporary biliary fistula after the removal of the gallstones.

**Extradural Abscess and Mastoid Disease.**—Dr. SEYMOUR OPPENHEIMER of New York read this paper. He said that quite often the channels of invasion were quite devious. Epidural abscess was the most frequent intracranial complication of mastoid disease. The abscess might vary in size from one containing a few drops of pus to one containing an ounce or more. The early symptoms of epidural abscess presented nothing to distinguish them from those of mastoid disease. If there was much increase in pressure an absolute recovery might be impossible. Usually there was a continuous headache over the affected area with a moderate elevation of temperature. Pain in the head was one of the most prominent and constant symptoms, and was usually present over the affected area. It was apt to occur in paroxysms, and the tissue over the painful area was sometimes exquisitely tender. If there was much meningeal irritation the pulse would become more rapid. If rigors were present, it was fairly certain that there was sinus involvement. If the differential diagnosis between abscess and meningitis could not be made by the symptoms, lumbar puncture should be resorted to. If, on opening the mastoid, the pus were seen to pulsate there was every reason to believe that it communicated with the cranial cavity.

Dr. FRANK W. HIGGINS of Cortland reported a case in which it was necessary to pass the aspirating needle down a distance of an inch and three-quarters into the brain before reaching pus. In cases of this kind, the operator desired very much to have some hint as to what was the best direction in which to pass the needle, and it occurred to him that as these abscesses were said to occur about three times as often in the middle as in the posterior fossa, this might serve as a guide to the operator.

**School Hygiene and the Great Need of Regular Medical Supervision.**—Dr. H. ERNST SCHMID of White Plains was the author of this paper. He said that the ideal classroom was oblong, measuring 10 feet wide by 25 feet long and 13 feet high, and having a seating capacity of forty pupils. Such a room gave 18½ square feet to each pupil, and 243½ cubic feet or air space. The light should always enter at the side, preferably the left, or at the side and back. Pupils in the primary department should not be kept seated more than one-third of the school time. There had been much discussion over the comparative merits of vertical and slanting writing. The former was the more natural. Statistics appeared to indicate that about 25 per cent. of the children were injured by being compelled against their natural bent to write a slanting hand. The glass space should be equal to one-fourth, or, better still, one-third of the floor space, and the shades should work from the bottom of the windows only. The walls of the school room should not be kalsomined but should be painted a greenish-gray color. The standard of teachers for the primary grades should be as high as for the highest classes, because their power over their little charges for good or evil was very great. The speaker urged that the medical profession should endeavor to secure a State law requiring all schools to be under constant medical inspection and supervision.

**The Influence of Oxygen Taken by Full Normal Respiration, When Chemically Pure, as a Means of Sustaining and Increasing Mental, Nervous, and Physical Energy.**—Dr. CORDELIA A. GREENE of Castile was the author of this paper, which was read by Dr. Walsh. She stated that she had been employing oxygen by inhalation for more than fifteen years, and had observed the most marked therapeutic effects from its use. There was no better aid to recovery from bronchial irritation. In all cases in which there was deficient vesicular respiration because of congestion, non-use or anything else, oxygen was valuable. As full nervous vigor depended so intimately upon effective oxygenation, it was easy to understand how this gas was useful in all cases in which there was nervous debility. The air should be fresh, and not over 65° F. in the inhaling room. After having taken a deep inhalation of the gas the breath should be held for a short time, and this should be followed by a deep inspiration of ordinary air. At one seance not more than ten or twelve oxygen inhalations should be taken. Such treatment always tended to make the patient feel quiet and restful.

Dr. DELANCEY ROCHESTER of Buffalo said that some years ago he had been an ardent believer in the efficacy of oxygen inhalations, but having observed two series of cases of young anæmic women, one treated by such inhalations and the other simply by fresh air and exercise, he found that, if anything, the results in the latter class were better than in those treated with oxygen.

Dr. C. E. QUIMBY of New York said that in pneumonia the trouble was not only that there was not enough oxygen, but the patient could not get rid of the carbon dioxide. It was, therefore, quite as dangerous to use too much oxygen as not to give any at all to the pneumonia, because an excess of oxygen led to the retention of the carbon dioxide in the system. He had seen serious results in actual practice from this very cause.

**Bacteriology and Pathology of Dysentery in Children.**—Dr. WILLIAM H. PARK of New York presented a communication on this subject. He said that in this locality amœbic dysentery in children was practically unknown, but cases were met with in the Southern States. Although the Shiga bacillus resembled the colon bacillus, it was as distinct from the latter as was the bacillus of typhoid. Shiga had found it in every case, and had produced dysentery artificially by means of it. Summer before last the discovery had been made that the bacillus was found in Baltimore in children suffering from summer diarrhœa, a fact which for a time caused considerable confusion. During the past summer a number of investigators had been engaged along this line of research in and about New York City. Investigation showed that the bacilli of diarrhœa which had been thought to be the same as the original Shiga bacillus were, indeed, present, but mixed in with these cases were atypical ones associated with bacilli of what was called the acid type. These latter resembled the Shiga only in certain respects. There were apparently several groups of cases, viz.: (*a*) Severe cases characterized by necrosis of the mucosa and the appearance of the formation of a pseudomembrane; (*b*) cases in which there was a hyperplasia of the lymph follicles, both agminated and solitary; (*c*) cases characterized by superficial necrosis and ulceration of the mucous membrane, not limited to the follicles and not accompanied by the formation of pseudomembrane, and (*d*) a large group of cases showing very few lesions under the microscope, and no lesions at all on gross examination. The cultures from all of these cases showed only a few bacilli of the acid type.

*Serum Therapy.*—Dr. PARK said that during the past summer the serum treatment had been tried in a number of cases. By injecting horses with the Shiga bacillus one obtained, after from four to six months, a bactericidal serum which would protect against a moderate number of fatal doses. Shiga had reported favorably on this serum treatment. The serum used by Dr. Park the past summer was not that prepared by the New York City department of health, but that produced under Dr. Flexner's supervision, because it was felt that in a scientific investigation of this nature one should exclude, so far as possible, all possible sources of error. Cases occurring in both children and adults, and in various localities were observed, and the acid type of bacillus was identified in them. As was well known, most of the cases in this climate were quite mild. About fifty cases had been under observation, and about one-half of these received the serum, the others being kept as controls. In some cases, on giving twenty to thirty cubic centimeters on three consecutive days, there was no evidence of improvement, but they were not made worse. Some of the cases of a severer type did seem to show more improvement than cases of the same class not receiving the serum. The improvement was usually noted after the second dose, but the results were not very marked. The speaker said that from this experience he would certainly advise the use of the serum. It was hoped better results would be obtained in the future, for it had not been known until this recent experience that the two classes of bacilli differed so much, and hence, they had proceeded on the assumption that the same serum would answer for both classes of cases. This addition to our knowledge would not, however, lead to so much confusion as one might at first suppose, for it was found that one horse could be injected with two or more kinds of bacilli, and that by this method a serum could be obtained which possessed a wider range of usefulness. Of course, such a method would not be applicable to the cases occurring in other climates. He hoped those practitioners throughout the State who met with much dysentery would avail themselves of the offer of the health department to supply the serum, and would in this way coöperate in this interesting and important investigation.

Dr. CHARLES G. KERLEY of New York said that he had used the serum in about twenty cases. In two or three of these such improvement had been noted as to suggest that the serum had caused it, but at the present time he was only willing to express the opinion that the serum treatment appeared to have a promising future, and that it certainly did not harm.

**Radium in Medicine.**—Dr. SAMUEL G. TRACY of New York presented this paper. He pointed out that pure radium salts evolved enough heat to melt more than their weight in ice every hour, and yet at the end of months the radium was as potent as before, and one could observe no change in its weight or by chemical, microscopical, or spectroscopic examination. This substance had thrown the first doubt upon the law of the conservation of energy. If a small glass tube containing radium were kept in the vest-pocket for several hours it would cause a severe burn, but the full physiological effect would not be noted for a week or ten days. Seeds exposed to radium for several hours lost their germinating power. As yet comparatively few physicians had reported upon the use of this wonderful substance in deeply seated cancer, yet there was reason to believe that it might prove very useful in such cases as well as in lupus, rodent ulcer, and superficial cancer. Radium was known to possess bactericidal power, and it had been inferred from this and its other properties that it should prove beneficial in pulmonary tuberculosis. Specimens of radium were exhibited, and the attention of those present called to the fact that pure radium did not fluoresce, but that fluorescence was observed when radium was more or less adulterated.

**Some Less Usual Causes of Post-operative Elevations of Temperature.**—Dr. MARTIN B. TINKER of Clifton Springs read a paper on this topic. He said that small pulmonary emboli, which were often overlooked, were the cause of post-operative fever in some cases which seemed puzzling because of the absence of any obvious cause for the fever. Some observers were inclined to believe at the present time that all postoperative pneumonia was embolic, and was not, as formerly believed, an aspiration pneumonia. Pericarditis was a very infrequent cause of fever after operation. Cerebral embolus occasionally acted as such a cause. In one case of this kind, although there was no fever prior to the cerebral embolism, it was quickly followed by a temperature of 104° F. Phlebitis and thrombosis of the femoral vessels were occasionally seen after abdominal operations. The speaker reported several cases in which the saphenous veins were so affected. It was not fair, he said, to ascribe a post-operative rise of temperature to malaria unless the parasite of malaria were found, but in these cases, it must be admitted, it was often very difficult to detect this organism, particularly as these cases were apt to be of the estivoautumnal type. Many of these patients had no fever before operation.

Dr. ELIAS LESTER of Seneca Falls remarked that he lived in a malarial region, and so commonly did a malarial element creep into various diseased states, notably in pneumonia and in the puerperium, that he found it desirable to give quinine as a prophylactic.

Dr. WILLIAM B. ULRICH of Chester, Pa., said that he did not believe malaria or intermittent fever was always produced by the bite of the mosquito. He had been in active practice for twenty years in Louisiana, and in the very years when mosquitos were most plentiful, *i.e.* in the years of overflow, intermittent fever was at a minimum. A malarial element entered and altered the clinical picture of almost all the acute diseases in that state. He had lived in Delaware County before intermittent fever was known there, and in Chester County this disease was unknown until a railroad was built in that region. The city of Chester was rapidly built up, but malaria did not make its appearance until later on, when the march of improvement led to extensive excavations of the earth. Nevertheless, during all this time there existed along the Delaware river the same marshes and lagoons.

*Wednesday, October 21—Third Day.*

**Ergot in Alcoholism and Morphinism, and the General Class of Drug Habit Cases.**—Dr. ALFRED T. LIVINGSTON of Jamestown was the author of this paper. He said that he was totally opposed to the theory that the drug habitué was the subject of a specific disease which impelled him to the special habituation. He denied *in toto* the existence of such specific disease, but, of course, he did not deny that diseased states resulted from the improper use of such drugs. On attempting to leave off a drug to which one had become addicted the resulting disturbance of the nervous system was proportionate to the daily dose of the drug that had been taken. It was the sense of restlessness within that suggested a renewed application of the drug. The speaker protested earnestly against the too common practice of many medical men of using too frequently, and generally absolutely unnecessarily, the whole class of narcotic stimulants. Sleeplessness, pain, and restlessness could be more surely relieved by ergot than by this class of narcotic drugs. He believed that the nervous disturbance depended upon the disturbance of the vascular system, hence, the indication was to bring about, as promptly as possible, an equilibrium of the circulation. There were several methods by which this could be done. One method was by cold to the spine, or hot sponging followed immediately by cold sponging of the spine. Another method was galvanism of the chain of sympathetic ganglia by the use of hand electrodes, stroking downward from the occiput to the sacrum with the electrodes held about four inches apart. A current of 10 to 15 milliamperes should be employed for this purpose, and the

application should be continued for ten or twenty minutes. This should be followed by a short application to the cervical ganglia. A prolonged application of the static wave current to the whole length of the spine was also exceedingly useful.

**The Ergot Treatment of Drug Habits.**—He considered the hypodermic injection of ergot the most certain of all the methods for restoring the equilibrium of the circulation. Ergot contracted the sort of muscular tissue of which the muscular coat of the blood vessels consisted, but its most pronounced action was upon those areas of such tissue as were weak and relaxed; hence, its action on ditated blood-vessels was peculiarly satisfactory. This method of administration placed the drug most surely and promptly where it would accomplish the desired purpose. It could, of course, be given by the mouth, but the only sure way was by putting it directly into the circulation. In the past few months several drug houses had removed the former objections to the hypodermic use of ergot, so that now this drug could be given subcutaneously with little or no inconvenience. In the treatment of these drug habits the first step was wholly to discontinue the use of the narcotic, and place around the patient such safeguards as would entirely prevent the taking of the special drug or of any substitute therefore. He began at once the administration of ergot, because he knew that in twenty-four to thirty-six hours there would be a violent reactionary stage characterized by marked circulatory disturbance. At the same time that he began the use of the ergot he gave a purgative. He made use of the fluid extract of rhamnus frangula, in doses of one or two drachms at bed-time, and sometimes also morning and afternoon, in order to keep the bowels open. In general, two or three doses of ergot of half a drachm each of his solution should be given *per diem*, but in extreme cases it might be necessary to employ this drug at intervals of two hours. The morphine habit was the most difficult of all to cure, yet the ergot method of treatment acted admirably even in such cases. He would not hesitate to treat such a case in any well-regulated hospital. In no case, after the first forty-eight hours, had he had a request from the patient for this drug or a substitute for it, nor had he seen in any such case, any evidence of such desire. It was desirable to avoid even the use of hypnotics, for sleep could be secured without these drugs, and, if necessary, he would make use of all the methods spoken of at the beginning of this paper. A modified plan, sometimes useful, was to give hypodermically one or two doses of ergot daily, combined with a fractional part of the former daily dose of the drug employed. The next day this small dose of the narcotic should be reduced one-half, and this method of gradual reduction should be continued until the eighth day, when the drug should be entirely discontinued. The fact of the administration of the morphine wit hthe ergot should be kept from the knowledge of the patient. This modified method was never required in any but the severe forms of morphine and opium habit. The thallate of morphia was the best preparation for such purpose. He had abundantly demonstrated the success of this method, which, he believed, had a thoroughly rational basis.

Dr. ALEXANDER LAMBERT of New York said that he had had a very large experience in Bellevue Hospital in the treatment of severe cases of confirmed alcoholism. For years each service of six weeks had yielded twenty-five or thirty deaths; but since he had made use of Dr. Livingston's method of using ergot, the six-weeks' service had given only six or seven deaths. Persons entering the hospital on the verge of delirium tremens were given a drachm of paraldehyde in some whiskey. This usually gave refreshing sleep for several hours. Very obstreperous patients were given a hypodermic injection of apomorphine and ergot. They would almost immediately become calm and limp, and if wrapped up in a warm blanket would sleep for several hours. The same thing happened with apomorphia alone, but if ergot were added, the patient would awaken in much better condition. He ordinarily administered 30 minims of a 12½ per cent. solution of ergot, repeating it in an hour and afterward at intervals of two hours. Perhaps the most extraordinary action of ergot was in what were known as "wet brain" cases. In past years Dr. Lambert said he had tried every known method of treatment that offered any chance of success, but the best he could do was to save three out of one hundred of these patients. To his utter astonishment he had been enabled by the ergot treatment to save all but two in about thirty cases, instead of losing all but three in one hundred. An autopsy on one case showed a remarkably dry brain, showing that the ergot had prevented the occurrence of serous exudation.

In treating the morphine habit in these wards unusual difficulties were encountered. He had, therefore, adopted the method of cutting off the morphine in the course of forty-eight hours, thus avoiding excitement and violent opposition.

Dr. FREDERICK HOLME WIGGIN of New York said that he had found the hypodermic use of ergot useful both in delirium tremens and in insomnia, but he had not obtained good results with less than 50 or 60 minims at a dose.

**Laboratory Aids to Diagnosis for the General Practitioner.**—Dr. V. A. ROBERTSON of Brooklyn was the author of this paper. He said that a laboratory could be fitted up at slight cost, the chief expense being the microscope. The latter should be provided with ⅔-inch and ⅙-inch dry objectives and a $\frac{1}{12}$ oil immersion lens. Examination of the sputa for tubercle bacilli should certainly be made by the physician himself. In recent years so much aid had been derived from blood examinations that the up-to-date physician felt the necessity for adding these to his resources. The occurrence of leucocytosis was of great diagnostic value. Its absence in certain affections in which it would be naturally expected to occur afforded a useful hint. Leucocytosis was absent in malaria, most cases of influenza and measles. If found during the course of typhoid fever, it might point to impending perforation of the bowel. The number of leucocytes in any acute infection was said to be directly proportionate to the intensity of that infection. The diagnosis of malaria should never be based upon the clinical symptoms alone. The Widal reaction could not readily be made by the general practitioner unless he could obtain a fresh culture of the typhoid bacillus. Ehrlich's diazo reaction was within the reach of the general physician, and although present in other diseases, it was of considerable value in the diagnosis of typhoid fever. The diagnostic value of the pneumococcus was undisputed, and this organism could often be recovered from the sputum before the physical signs warranted a diagnosis of croupous pneumonia. The examination of the gastric contents was of great diagnostic value, and should be more commonly employed in general practice. In case of dysentery the fæces should be examined for the amœba coli.

Dr. DE LANCEY ROCHESTER cited some cases to illustrate the practical value to the physician of resort to laboratory methods. He also recalled the fact that recent investigation showed that if the small fibrinous plates found in pleuritic exudates were partially digested, tubercle bacilli would almost invariably be found.

**Treatment of Puerperal Sepsis.**—Dr. JAMES HAWLEY BURTENSHAW of New York presented this paper. He said that the treatment should aim to remove the source of infection, and neutralize the effects of the septic germs or of their toxins and support the patient's vitality. He believed curettage of the septic uterus with a sharp instrument to be unjustifiable, but recommended the removal of retained secundines by means of a finger or a dull wire curette. Lacerations of the cervix and vagina should be cauterized, and the cavity of the uterus

should be irrigated with two gallons or more of warm salt solution, or 1-per-cent. lysol solution. Both cavities should then be packed with 10-per-cent. iodoform gauze. He has never obtained as satisfactory results from the use of vaginal or uterine tampons soaked in formalin or alcohol, and did not favor continuous irrigation of the uterine cavity in cases of infection, as the pathogenic organisms were lodged beyond the granulation wall. In sapræmia, however, such irrigation might be of benefit. The treatment of puerperal sepsis by hysterectomy had not met with general approval. To neutralize the effects of the germ invasion he believes the functions of the kindey and bowel should be promoted. The administration of antistreptococcic serum had been disappointing, as had the intravenous use of formalin solution. Opening and packing of the posterior cul-de-sac with iodoform gauze was to be commended. Considerable stress was laid on the good effects obtained from the use of normal salt solution. It was still a mooted question as to the manner in which the solution exerted a favorable influence, but the term *lavage du sang* would appear to be particularly significant in this connection.

To support the patient's vitality it was advised that the diet be nutritious to the last degree, and easily digestible. He believed strongly in the administration of brandy or whiskey in liberal doses, not only for their stimulating effects, but as a food. Ergot, strychnine, and quinine were always indicated. The temperature should always be controlled by means of cold sponging; never by antipyretic drugs.

Dr. Joseph B. Cooke of New York spoke of prophylaxis, and stated that there would be less liability to puerperal sepsis if the physician would make it a routine practice to hold the uterus for an hour after delivery, thus securing firm uterine contraction and avoiding the lodgment of clots in the uterus.

Dr. E. V. Delphey of New York advised washing out the uterus postpartum with very hot water containing enough tincture of iron to impart to it a port-wine color. For a number of years he had used digitalis with much satisfaction, not only to contract the uterus, but to strengthen the heart.

Dr. De Lancey Rochester said that in modern obstetric practice puerperal septicæmia was chiefly seen in connection with gonorrhœal infection. When such infection was known to exist, a douche of hot iodine water, of the strength of a tablespoonful of the tincture of iodine to the quart, should be given after labor, and whenever practicable iodine should be used locally for a month or two prior to labor.

**When and How to Operate for Gallstones.**—Dr. Irving S. Haynes of New York read this paper. He said that only about 5 per cent. of cases of cholelithiasis became active, but evidence of activity might arise at any time without warning. Late operations were usually complicated ones, and carried with them a death rate of 40 per cent.; on the other hand, early operations were usually successful. The symptoms which would most constantly lead to a correct diagnosis were not biliary colic and jaundice, but digestive disturbance, a feeling of weight or burning in the vicinity of the stomach after eating, gaseous distention of the abdomen, a dull pain around the right side of the abdomen at the level of the gall-bladder, and a point of tenderness in this region. There might also be a history of one or more attacks of supposed appendicitis or of typhoid fever. Sometimes there was a barely perceptible yellow tinge of the skin, not amounting to jaundice, noticeable at the time the patient was feeling badly. The area of liver dulness was usually increased. According to Ochsner's experience, jaundice was absent in 75 per cent. of the cases, the pain was usually in the pit of the stomach, and there was often a tender point situated an inch and a half to the right and above the umbilicus. The search for calculi in the fæces was often disappointing, and even if calculi were found, this was no proof that others had not been left behind, which might eventually cause a return of the trouble. Attacks of colic or of severe abdominal pain were absent in nearly half of the cases. When there was obstruction, there was apt to be sudden and irregular exacerbations of fever. When reasonably certain of the existence of cholelithiasis an operation should be undertaken. The mortality in early and uncomplicated cases was 2 or 3 per cent. An operation done at the time of election, or in an interval of colic, was usually fairly easy. In considering the choice of operation, it should be remembered that the gall-bladder, when once diseased, was useless as a receptacle for bile, and that a fair percentage of such cases terminated in carcinomatous degeneration. As ideal conditions were often absent, one should, in most instances, resort to simple incision and drainage. Even after excision of the gall-bladder stones might form in the ducts themselves. If calculi were discovered in the ducts, they should be removed if possible.

**The Typhoid Epidemic in Ithaca, with Special Reference to Causation, Prevention, and Treatment.**—Dr. Chauncey P. Biggs of Ithaca read a paper with this title. He said that the specific source of infection could be more easily traced when it occurred in the milk, than in the water supply. The exact source of infection of the water of Ithaca had not yet been satisfactorily demonstrated. The epidemic had presented many points of resemblance to the epidemic at Plymouth. It was estimated that about one thousand cases developed during the first six weeks of the epidemic. There were probably very few of the citizens who did not, at some time or other, drink some of the infected water, and yet the number of isolated cases outside of the infected district was quite small.

**President's Address: The Past and Present Needs of the Medical Profession.**—Dr. Frederick Holme Wiggin delivered this address. He said that the development of medical organization was largely limited to State and county bodies until 1847, when many of the existing societies organized a national organization, the American Medical Association. The present condition of the medical profession was well shown by the frequency of malpractice suits, the flagrant abuse of medical charity and the extent to which contract practice is carried. A recent speaker had aptly remarked that "a physician may be prime minister of France; he may be governor of Cuba, but he cannot become president of the New York City Board of Health." Victor Horseley, in a recent article, recognized the importance of medical societies taking part in both social and scientific work. He advocated united effort to protect the rights of the physician and defend him from unjust attacks. The requirements of medical education were becoming more and more exacting, resulting in great good to all concerned. It would be fortunate if our medical schools would give some instruction in the history of medicine. If our profession was to be organized into a body of sufficient strength to accomplish what was needed, the fundamental idea of organization must be better understood by all, and the plan of organization must be such as to secure control by the majority, and not by the minority. The local association should be made the door of entrance to and exit from the larger societies. Such organization must be powerful enough to prevent further demoralization of the public by an extension of the abuse of medical charity. It must discountenance contract practice in lodges and societies at ruinous rates, and must defend its members against unjust attacks upon their professional honor and standing. It must establish medical libraries and bureaus of information in the large medical centers for the benefit of its members, and should provide a death benefit fund. Such organization should have separate meetings for political and for scientific discussion, and means should be provided for the proper

publication of its scientific proceedings. In order that the association might carry on its work properly there should be an assured and ample income. The national organization should hold a charter of incorporation from the national government, not only to secure the requisite dignity and importance, but to facilitate the transaction of business in any State of the Union. The national association should from time to time publish a national medical directory, the data for which should be furnished without expense to it by the component societies. The officers of our associations should be medical statesmen, and the members should be taught a greater individual responsibility. The evils from which our profession was acutely suffering were the result of the mistakes of our predecessors. A long advance step had been taken by the agreement of the two State organizations of New York to form one society which would be worthy of the Empire State.

**Sewage Disposal as a Means of Purifying the Water Supply of the Cities and Towns of the State.**—Dr. CHARLES B. KEPT of Utica read this paper. He said that if the native purity of the Adirondacks were to be preserved the pollution of its waters must cease. The utility of intermittent sand infiltration for the sterilization of sewage had been fully demonstrated, and this method should be generally adopted; it was practicable on the farm, in the town and in the city. A filter that would meet all the requirements of the farm could be cheaply constructed. It should measure 15 by 20 by 5 feet and be divided in its long diameter by a partition through which sewage could not pass. On the bottom should be laid tiles graded to a common center. Over this, five feet of clean sand of suitable quality should be placed and given a proper slope. Only one of the two beds should be in operation at a time. The sewage should be well mixed before placing it on the filter, and each bed should be used alternately for periods of three days. Such beds had been in continuous operation for fourteen years at the experimental station at Lawrence, Mass. The cost of construction was nominal.

**A Man from Whom the Superior Maxilla on the Left Side was Removed in 1870.**—Dr. DAVID P. AUSTIN of New York presented the patient and reported the case for the first time. When first seen, there was a fistula beneath the left eye which was constantly discharging pus. The man had worked in a match factory for nearly sixteen years, and was suffering from necrosis of the maxilla as a result of the exposure to the fumes of phosphorus. The operation of removal of the maxilla was performed on May 4, 1870. Very free hemorrhage was encountered, but finally the whole bone was disarticulated and brought away in one mass. The case healed kindly and left almost no scar.

**The Treatment of Pneumonia.**—Dr. DELANCEY ROCHESTER of Buffalo read this paper. He said that the chief cause of death in pneumonia was failure of the circulation through degeneration of the myocardium. This degeneration was due to toxæmia and to morbid changes in the lung, causing obstruction of the circulation in the right heart. Sometimes uræmia was added to the toxæmia of the invading organism. The most common complications of pneumonia were meningitis, pericarditis, endocarditis, nephritis, and empyema. The indications for treatment were: (1) The relief of the toxæmia; (2) prevention of heart failure, and (3) meeting the complications as they arose. The use of stimulating diuretics was positively contraindicated. The first indication for treatment, *i. e.* the relief of toxæmia, should be met by inducing diaphoresis and mild catharsis. The sweating was most easily induced by hot mustard foot-baths given in bed, without disturbing the patient. The patient, nude, lay between blankets with the knees flexed, and the feet in a tub containing hot water and a heaping teaspoonful of mustard. From two to five blankets and a rubber sheet were placed over the patient, and the bath was kept up for thirty to forty-five minutes, according to the effect produced. Meanwhile cloths wrung out of ice water were kept constantly on the head. This sweating was one of the most important therapeutic measures. Catharsis should be induced by calomel, and maintained moderately by a daily dose of a saturated solution of Epsom salts. Frequent cleansing of the mouth with a mild antiseptic solution seemed to him a measure of considerable importance. The diet should be fluid and, so far as possible, sterile. Plenty of pure or alkaline water should be given in small quantities at short intervals. The sick room must have sunlight and plenty of fresh air. A physical examination of the chest should be made at every visit, and as soon as there was evidence of congestion in any portion of the lung, vigorous measures should be taken, such as the application of leeches, wet cups or dry cups. In this way the congestion would be prevented from spreading. His preference was for the first two. The cups should be left on for half an hour, and should be reapplied every four to six hours. He had observed post-mortem, the direct anatomical evidence of the value of this procedure. A light woolen jacket should be worn by the patient; the poultice jacket should be relegated to the dark ages. If there were evidence of obstruction of the right heart, from eight to twelve ounces of blood should be taken from the median vein of the forearm, a procedure which could be repeated, if need be, several times during the course of the disease. A little digitalis might be given at this time. After venesection, if heart-failure threatened, and there was no distention of the right heart, saline infusion or hypodermoclysis was useful. If more than one lobe of the lung were involved, oxygen gas should be inhaled at regular intervals. Direct stimulation of the heart should be begun just as soon as the diagnosis of pneumonia was made. Strychnine should be given hypodermically at intervals of four or six hours. Alcohol was the next best stimulant. In alcoholic subjects it sometimes caused cerebral excitement, and if so, ammonia should be substituted. If the bowels and skin were kept active it was seldom that resort to hypnotics became necessary. He desired to protest against the treatment of pneumonia by the use of large doses of digitalis in the early stage of the disease. His own record, with this plan of treatment, was 210 cases of pneumonia with 23 deaths.

Dr. A. ALEXANDER SMITH of New York said that the abstraction of blood in pneumonia was sometimes very useful, but he greatly preferred venesection to the use of cups, because the latter disturbed the patient too much. He did not believe it was possible to abort a pneumonia, although willing to admit that the disease sometimes aborted itself for some unknown reason. He had observed from the salicylate treatment of pneumonia, and believed it had not been generally accepted by the profession. He had used the creosote treatment in all classes of cases, and had never seen a lobar pneumonia, not complicated by general bronchitis, benefited thereby, but this treatment was beneficial when there was a general bronchitis in addition to the pneumonia. He was of the opinion that the tendency to heart failure in pneumonia was chiefly due to the action of the toxins on the nervous system, and in this way he explained the action of strychnine in improving the circulation. He was opposed to the plunge bath in pneumonia, and preferred a wet pack at 80 or 90° F. to sponging. Such a pack often slowed and strengthened the pulse. The application of either heat or cold seemed to act as a respiratory stimulant, and it apparently made no difference whether the application was made over the affected area or elsewhere. He held oxygen in high esteem as a therapeutic agent in pneumonia. When there was a tendency to cyanosis the vasodilators, such as nitroglycerin, were exceedingly useful. He had discarded ammonium chloride and carbonate in favor of the aromatic spirits of ammonia.

Dr. WILLIAM P. NORTHRUP of New York said that it was always very painful to him to see a child with a temperature of 105° F. tightly swathed in a poultice. He had

found the plunge bath exceedingly beneficial and quieting to those suffering with alcoholic pneumonia. Flatulent distention of the abdomen should be avoided, and the pneumonia patient should be given fresh air without stint.

**Arteriosclerosis and Its Bearing on Certain Lesions of the Retina and Optic Nerves.**—Dr. CHARLES STEDMAN BULL of New York presented this paper. He said that he regarded many cases of so-called chronic glaucoma as the result of atrophy of the nerve from retrobulbar arteriosclerosis. A pressure atrophy of the optic nerve within the cranial cavity might be caused by pressure of diseased and rigid vessels in crossing each other's course. The resulting atrophy of the nerve was at first a pure pressure atrophy; later on there was probably added a secondary proliferation of connective tissue, which caused more extensive atrophy and, perhaps, the formation of new vessels. The therapy of arteriosclerosis was still in its infancy. When the stage was reached at which the evidence could be recognized by the ophthalmoscope, the process must be far advanced. All that could be done was to arrest the progress of the disease and limit its extension. In the long-continued use of iodide of potassium we had an excellent means of arresting or retarding the extension of the process. When the underlying toxic influences were known they should, of course, receive special attention.

**Dysmenorrhœa.**—Dr. CHARLES BONIFIELD of Cincinnati, Ohio, was the author of this paper. He said that probably the commonest cause of dysmenorrhœa was lack of development of the uterus. Other causes were adhesions of the uterus, exfoliative endometritis, stricture of the cervical canal from the use of caustics, disease of the tubes, and deficient development, adhesions or prolapse of the ovary. Anæmia was, perhaps, the most important of the constitutional causes of dysmenorrhœa. Pain referred to the hypogastric region pointed to a uterine origin; if the pain were greater during the flow, and was not apparently associated with uterine contractions, a constitutional cause might be suspected. Pain in the iliac region pointed to disease of the appendages. If the pain were not very severe, rest in bed and hot drinks and hot baths might be sufficient. In severer cases, drugs would be required. Opium and alcohol should be avoided, because of the danger of establishing a habit. The coal-tar products answered very well as substitutes, and, in his hands, a combination of atropine and sodium bromide had proved very useful. Viburnum prunifolium sometimes acted satisfactorily, but was uncertain. The salicylates were useful in rheumatic individuals. In cases of defective development, thorough dilatation of the cervical canal and curettage should be done, and in addition, the uterus should be packed with gauze, thus producing a miniature labor. Sometimes two or three such curettements would be required at intervals of a few months or a year or two. Malpositions should be attended to.

**Properties of the Blood Serum as Illuminated by Ehrlich's Researches.**—Dr. RICHARD C. CABOT of Boston gave a most interesting and instructive exposition of this highly intricate subject. He expressed the opinion that there had been no single medical discovery since the promulgation of Virchow's cell doctrine, as important as that comprising the facts and theories springing out of Ehrlich's researches. Until very recent years the blood serum had been looked upon as one of the most uninteresting of tissues. The discovery of Nuttall that the blood serum possessed bactericidal power attracted very little attention until the antitoxic studies of Roux and others. It should be recalled that a toxin was the filtered sterile product of a culture of some pathogenic organism. When such a toxin was injected into the blood, the toxin left the blood, often in a very few minutes. Ehrlich proved that it attached itself to certain body cells, exhibiting in this a selective action. A toxin never poisoned, as strychnine did, while circulating in the blood; its action was made manifest only when it combined with certain cells. The production of antitoxin in an animal was out of all proportion to the amount of toxin introduced. Ehrlich's ingenious and somewhat fanciful "side-chain" theory was really a metaphor, and was derived from chemical symbols. He conceived that the toxin molecule fitted what he called the receptor, as a key fitted a lock. The organs capable of being poisoned were those having receptors fitted for the reception of the toxins. The receptors were supposed to break off and swim freely in the serum. These receptors were the antitoxin. The ordinary function of the receptor was supposed to be to secure food for the cell. Dr. Cabot then went on to explain in detail the many fascinating features and ramifications of this theory, pointing out some of the medical and medicolegal possibilities resulting from the study of hæmolysis.

At the conclusion of the address, the association extended him a vote of thanks.

**Minus Cylinders; Those Who Prescribe Them, and Those Who Wear Them.**—Dr. FRANK W. HIGGINS of Cortland read a paper with this title. In it he reported a number of cases of eye-strain that had done very well under the use of minus cylinders. Incidentally, he paid his respects to the peripatetic opticians and "refractionists," who did so much harm, even when they were honest in their efforts, which was certainly not always the case.

(To be continued.)

## Medical Items.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 17, 1903:

SMALLPOX—UNITED STATES.

| | | CASES. | DEATHS. |
|---|---|---|---|
| Alabama, Mobile | Oct. 4–10 | 4 | .. |
| California, Los Angeles | Sept. 27–Oct. 3 | 6 | .. |

### HIGH-FREQUENCY CURRENTS.*

By HENRY G. PIFFARD, M.D., LL.D.,
NEW YORK.

PROFESSOR (EMERITUS) OF DERMATOLOGY, NEW YORK UNIVERSITY; CONSULTING SURGEON CITY HOSPITAL; FELLOW NEW YORK ACADEMY OF SCIENCES, ETC.

If an electric current alternates or oscillates at a rate of a million times or more per second, it may with propriety be termed a "high-frequency" current. Such a current was introduced into practical medicine by Dr. William J. Morton in 1881.† It enjoyed a certain measure of vogue among those who employed static electricity in the treatment of disease but its use was somewhat curtailed by the subsequent introduction by Dr. Morton of what is known as the "wave" current. This appeared to possess a wider field of usefulness than the earlier current to which the name Static or Franklinic induced current had been applied.

The brilliant experiments of Tesla with high power, high-frequency currents, induced D'Arsonval of Paris to study them carefully with a view to their utilization for therapeutic purposes. The result was the introduction of his high-frequency apparatus, the currents from which have been shown to produce very remarkable and very desirable results. It is to the currents from this apparatus with its various subsidiary appliances that the term "High-frequency" should be confined and is confined by all European authors.

I urge this, as high-frequency currents can be produced in various ways, but the currents themselves differ materially in character and can hardly be expected to produce exactly the same effects.

Three years ago I introduced still another high-frequency current, to which I gave the name "hyperstatic," in order to indicate its origin, and also to prevent its being confounded with the high-frequency current of D'Arsonval.‡

In order to make the matter clear I will indicate the manner in which these several currents are produced. To obtain the Morton "Static-induced" current you attach the leyden jars in the usual manner to a static machine. Then connect the patient to the outer armatures of the jars. Bring the sliding poles into contact and start the machine. Then separate the poles a short distance (say an eighth of an inch). The patient will now experience a slight sensation. If the spark-gap between the poles be increased to a quarter of an inch, distinct muscular contractions will take place, and if the gap be further increased the limit of the patient's endurance will soon be reached.

The D'Arsonval apparatus consists essentially of the following parts: (1) A good high-tension spark coil rated at eight or ten inches; (2) an efficient interrupter in the primary circuit; (3) Leyden jars or some other form of condenser of suitable capacity and (4) a solenoid. In other words, the simple addition of a solenoid to any *x*-ray outfit.

If the reader wishes to understand fully the D'Arsonval current let him connect the Leyden jars or other condenser to a static machine or coil. If now he takes a piece of wire and coils it helically so as to convert it into a solenoid, and attaches it to the outer coats of the jars with the electrodes attached to the same points and holds one in each hand, he will experience no sensation, but he must not deceive himself with the idea that there is "nothing doing," for if he will bring his hands close together, say within a quarter of an inch of each other, he will be promptly convinced to the contrary. This current which traverses the patient without giving rise to any special sensation is D'Arsonval's high-frequency current, and the only current to which, under this name, the European literature of the last ten years applies. It is only obtained when the patient is in a circuit *in shunt* to a suitable conductor connecting the external armatures of the condensers. It will be noted that there is *no spark gap* in the circuit of which the patient forms a part. The fact that a strong current passes through the body when in shunt to the solenoid may at first appear a matter of surprise, but it is due to the heavy impedance developed in the solenoid by the self-induction of the several coils of the solenoid on each other. In France an induction coil is universally employed in generating the D'Arsonval high-frequency current, probably because they have excellent coils in France, while their static machines are mere toys compared with those commonly used in this country. There is, however, a distinct difference between the high-frequency current from a coil and one from a good (American) static machine. The latter gives a current of higher voltage, but lower amperage.

D'Arsonval uses his high-frequency current direct from the solenoid, or in connection with two important subsidiary appliances. One of these is his condenser couch,§ which appears to me to be of but limited usefulness as compared with his large solenoid. This latter is about thirty inches in diameter and five or six feet high, large enough, in fact, to surround the patient without being in contact with him at any point. The terminals of the large solenoid are connected to those of the small solenoid,

*Read at a meeting of the Medical Society of the County of New York, September 28, 1903.

†Recent experiments by Dr. Manders (*Medical Electrology and Radiology*, July, 1903) appear to throw some doubt on this statement. According to this writer, the Morton arrangement gives rise to an interrupted, unidirectional current, and not to an alternating or oscillating one.

‡My hyperstatic transformer was at first made with the coarse wire inside the fine or secondary winding, the two being separated by modified form of the Tesla insulation. It was soon found better to reverse the arrangement, and to place the coarse winding outside the finer and using glass for dielectric. D'Arsonval also, in 1900, introduced his "Nouvelle bobine bipolaire," which involves a similar arrangement except that he depends on air instead of glass as the dielectric.

§A condenser couch can be readily arranged by taking a cheap examining table and laying a sheet of metal or wire gauze on the middle part. On this is spread two or three layers of cotton felt, over this again the thin mattresses or cushions that come with the table. The total expense need not exceed twenty-five dollars. Mr. Chisholm Williams has used the condenser couch with apparent benefit in the treatment of pulmonary tuberculosis.

and the passing current induces a corresponding current in the body of the patient within the coil. Physiological experiments by D'Arsonval and others have shown that the current induced by the large solenoid notably increases the respiratory exchanges, the excretion of the urinary solids (including urea, uric, and phosphoric acids), the toxicity of the urine, and the radiation of heat from the body. In other words, there is a decided increase in the general metabolism, or as a French writer expresses it: "*Une suractivité plus grande des combustions organiques.*"

FIG. 1.—Spiral.

When we consider the large number of affections now recognized as depending on or accompanied by defective or retarded catabolism, the physiological data above given will readily indicate the therapeutic measures that may with confidence be pursued.

In 1893 Oudin of Paris connected his "resonator" to the D'Arsonval small solenoid, and in this way materially increased the potential of the current. Its chief use is in the local treatment of diseases of the skin.

My own hyperstatic transformer (MEDICAL RECORD, October 20, 1900) gives a high-frequency current, but it differs from the D'Arsonval current by its higher voltage. I have used this current only for the local modification of lesions and for its derivative effects. Whether it possesses any constitutional action or is capable of in any way modifying metabolism, I do not know. When I have desired to influence nutrition or to stimulate metabolism by means of high-tension currents I have availed myself either of static electricity pure and simple, or have used the D'Arsonval current.

The fact that an insensible current (*i.e.* one that cannot be felt) produces such sensible effects has as yet received no adequate explanation. The fact, however, remains, and a very ready and convenient means of demonstrating it, is to put an ordinary 16 c. p. 110 volt lamp in series with the

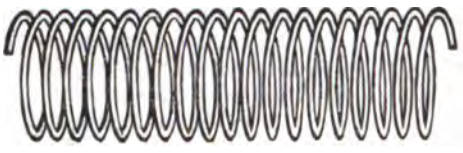

FIG. 2.—Solenoid.

human body, and passing the current derived from the small D'Arsonval solenoid. With a current of, say, six amperes traversing the primary of an eight-inch coil, the filament of the lamp will immediately become of a bright cherry red, and without causing the slightest sensation in the person through whom the current is passing. This means a current of between two or three hundred miliamperes. If a direct current of equal strength were passing, the electrodes would cause an unbearable burning pain, while if an alternating current of low frequency (a few hundred alternations per second) were used, there would be intense tetanization of the muscles.*

*The remarkable difference between the effects of low tension direct, and high-tension high-frequency alternating currents is well exemplified in the transmission of ocean messages. If a low-tension current is used, as from a large battery or dynamo, a metallic conductor traversing the sea must be employed. A high-frequency current, however, will flash the message over the ocean without the need of intermediate wires.

Having used the D'Arsonval methods to a considerable extent, and having become thoroughly satisfied as to their potency in local lesions and their great value in improving the general metabolism, it yet seemed that some slight improvement might be made in the electrical technique, still preserving the essential D'Arsonval feature—that is, placing the patient in shunt to the current passing through the small solenoid. To this end I substituted a spiral† for a helix, and after many experiments with spirals of copper, brass, aluminum, iron, and steel finally found one that gave me results superior to those obtained with the D'Arsonval helix—the superiority being due to the fact that the self-induction and impedance was greater with the spiral than with the helix, and the shunt current consequently stronger.

The spiral that I have found most satisfactory is seven inches in diameter and nine inches and a half in height, including the base. When used with the static machine, place the largest jars in position and connect the terminals of the spiral with the outer coatings of the jars, with the electrode cord connected to the same points. The subsequent technique is that of D'Arsonval, which, briefly stated, consists in (1) applying both electrodes (metallic preferred) to the patient: (2) connecting one in-

FIG. 3.—The author's high-frequency spiral for use with an *x*-ray coil.

different electrode (metallic) to the patient and bring a vacuum tube‡ near or in contact with the part that we desire to modify locally; (3) connecting one pole to D'Arsonval condenser-couch, the other pole being brought into contact with some part of the patient's body; (4) connecting the two poles with the terminals of D'Arsonval large solenoid or cage.

If the spiral is to be used in connection with an *x*-ray coil *medium-sized* jars are mounted on the same base with the spiral, the terminals of which are already connected with the outer coatings of the jars. (Fig. 3.) The inner coatings of the jars are then connected to the terminals of the secondary coil, and the apparatus is brought into action with such spark-gap between the secondaries as may be found

†A spiral is defined by the Standard Dictionary as follows: "Any plane curve formed by a point that moves around a fixed center and continually increases its distance from it." This is shown in Fig. 1. The solenoid or helicoidal employed by D'Arsonval is of the form shown in Fig. 2.

‡The use of vacuum tubes in connection with the therapeutic application of high-frequency currents is a purely American development, and the credit for their introduction belongs, I believe, to Dr. F. F. Strong of Boston. They are but little used or known in France or Germany, but have gained some favor in England.

necessary. If two identical spirals are used one with a coil and the other with a static machine, the resulting shunt currents will not be identical—the former having the higher amperage and lower voltage.

The large solenoid of D'Arsonval is open at the top, but in the one I have had made for my own use the wire is continued in the form of a horizontal spiral, forming in this way a top to the cage. (Fig. 4.) It increases the auto-induction and adds to the efficiency of the apparatus. If a current of six or eight amperes be passed through the primary of the *x*-ray coil, the patient within the cage will experience but little sensation, although a powerful current is circulating through him. This will be readily demonstrated if he will hold the outer terminal of an Edison 16 c.p. 110 volt lamp between his finger and thumb, and touch the inner or central terminal to one of the upper wires of the cage. The carbon filament immediately becomes

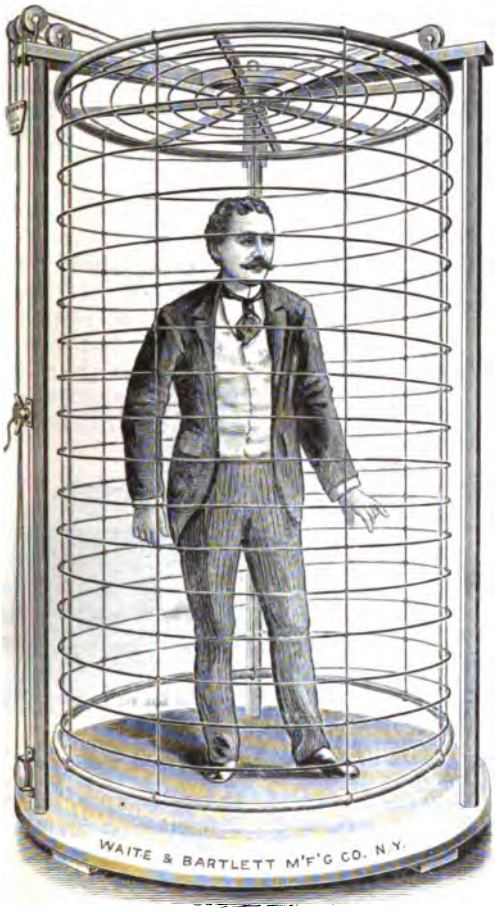

FIG. 4.—The author's resonator or combined spiral and solenoid.

of a bright red. The spark-gap between the terminals of secondary of the coil need not exceed one-half of an inch. If longer than this the lamp will short circuit inside, or, as sometimes happens, the lamp filament will instantly flash to a full brilliance and then break.

If, instead of connecting as above, one pole of the small solenoid or the author's small spiral be connected with the central terminal of the large flat spiral forming the roof of the cage, and the other pole to the point where the spiral joins the large solenoid, the induction effects are intensified as the arrangement now constitutes a large Resonator with the patient inside of it, instead of outside as with the Oudin. A still more intense effect is obtained if the small solenoid or spiral be omitted, and the outer and inner ends of the top spiral be connected directly to the outer armatures of the condenser (leyden jars). With the latter arrangement a longer spark-gap can be used. If connecting cords and electrodes are connected with any of the turns of the large coil, a regular D'Arsonval current with its secondary applications may be administered to one or more patients outside the solenoid. whether there is one within it or not: and this with but little apparent diminution of the intensity of the induced current within the cage.

I have not clinically used the large D'Arsonval solenoid in connection with a high-frequency current derived from a static machine, as my office arrangements will not conveniently permit of this combination. Experimentally it works in a satisfactory manner.

The very manifest difference between the wave-current of Morton and the high-frequency current of D'Arsonval immediately suggests the query as to the relative merits of the two in respect to their influence on metabolism. Clinical experience abundantly establishes the fact that both currents administered with care and judgment are capable of improving the various functional activities, including the respiratory, the thermogenic, and those relating to the conversion of ingesta into ejecta, be the same solid, fluid, or gaseous. The results of physiological experiment have shown the same in respect to the D'Arsonval currents, but I do not find that static electricity has been subjected to the same careful tests. Quite recently, however, some very careful and painstaking experiments with static electricity by MM. Maitre and Florence of Montpellier (*Archives d'Électricité Médicale*, April, 1903) have demonstrated that so far as the urinary secretion is concerned, the effects are similar in character but less in degree than those observed by D'Arsonval and others in connection with high-frequency currents. The machine employed consisted of two plates, capable of giving a spark of ten inches. It is to be regretted that the experimenters did not employ a more efficient apparatus. If this had been done it is quite possible that the metabolic results would have equalled, and perhaps surpassed, those obtained with the D'Arsonval system.*

It is now three years since I introduced the Hyperstatic Transformer for the local treatment of certain cutaneous lesions, and so far as I can learn the apparatus has given satisfaction to those who have used it. Some, however, I find do not appear to understand fully its capabilities or how to use it to

*One of the earliest static machines constructed in America for therapeutic purposes was copied, I believe, from one imported from France, and it is not a little surprising that the French have been so backward in the further development of this apparatus. The current advertisement of a somewhat prominent French manufacturer offers a "*Machine Statique a Grand Débit*," which consists of two pairs of plates twenty-two inches in diameter! A toy like this would not be seen in an American office, where it would be difficult to find a static machine with fewer than eight pairs of plates of thirty inches diameter. Static machines of the Wimshurst type are the ones commonly used in Europe, and in this type each pair of plates requires a separate belt. If a large number of plates are mounted it is almost impossible to secure uniform rapidity of rotation, which greatly impairs the efficiency of the machine. In this country the Wimshurst is not manufactured for therapeutic purposes, but the prevailing types are the Holtz and the Toepler-Holtz. The latter is self-exciting and proves attractive to some, on that account, as well as by reason of the lower price at which it can be manufactured, but the writer's experience with it is far from being as satisfactory as with the Holtz machine, which requires an independent exciter. If a Holtz and a Toepler-Holtz have equal areas of revolving surface, the output of current will be greater from the Holtz; when in action the Holtz machine will not change polarity, which the Toepler-Holtz is liable to do, especially when under a heavy load, when using the wave current or a high-resistance *x*-ray tube.

the best advantage. To these I offer the following suggestions:

Having connected the transformer to the static machine (with poles in contact), turn on the power, and when the plates are revolving at about 300 or 350 times a minute, separate the poles about an inch. If the hand be brought near one of the terminals of the transformer, it will be met by a diffuse electric spray (*effluve* of the French). The same will occur when the hand approaches the other terminal, but it will be noticed that the spray is more intense at one of the terminals than at the other, and it will be found that the stronger spray will be opposite the positive pole of the static machine. I usually connect the electrode with this terminal. If a very mild effect is desired the other terminal of the transformer is left free. If a stronger effect is desired the inactive terminal is grounded, and if still more action is required this terminal is connected with some part of the patient's person. The strength of the current may be further modified by using a longer or shorter spark-gap. After studying the effect of the spray the electrode should be brought nearer the skin, and when sufficiently near, bright sparks will shoot forth to be replaced by a multitude of fine sparks when the electrode is brought in direct contact with the skin. The best spray effect and also the strongest sparks are obtained when using an electrode with a metal point. The most generally useful electrodes, however, are glass vacuum tubes. I use a dozen or more of these, of shapes adapted to the particular requirements of the case. Some are of low and others are of comparatively high vacuum.

The transformer may be used with an *x*-ray coil by connecting it to the terminals of the secondary wire of the coil and adjusting the spark-gap of the coil so that the length of the spark shall be one-half inch or less. As the current delivered by the coil differs from that of the static machine (being of higher amperage and lower voltage), the current from the transformer will be somewhat modified. The spray will be shorter, more compact, and finer; while from the vacuum tubes the sparks are much finer and more numerous. On the whole, I find the current from the transformer connected with the static machine more effective than when connected with the coil. If the experiments are conducted in a darkened room the luminous effects are very striking.

As I have endeavored to make clear, the functions of the hyperstatic and the D'Arsonval currents are quite different and distinct—the former being chiefly useful for local applications while the latter is capable of distinctly influencing the general system.

Nearly thirty years ago the writer became fully satisfied that in the majority of cases of chronic eczema there co-existed a condition of the system characterized by defective elimination of catabolic products, and he so expressed himself as fully as the facts then appeared to warrant.*

From that time to the present I have found no good reason to question soundness of the views then put forth, although they have not been generally accepted by dermatologists, many of whom are inclined to attribute the phenomena that accompany eczema to a local pathogeny.

If we rely on drugs to facilitate the elimination of these "*materies morbi*," or elements of autointoxication, we have at command diuretics, cathartics, diaphoretics, alkalies, and substances belonging to the salicylic group, but none of these has in my hands yielded results as satisfactory as may be obtained from high tension electricity, whether through the Morton wave or the D'Arsonval high-frequency currents.

When I have desired to obtain both the constitutional and local effects of high-tension electricity, I have until recently employed the wave or the D'Arsonval followed or preceded by the hyperstatic. This in many instances was tedious and time-consuming.

It then occurred to me to put binding-posts on the outside of the hyperstatic case and connect them with the terminals of the primary coil, leaving all other connections as before. If a patient be now introduced into this primary circuit he will receive the pure D'Arsonval current, and a 16 c. p. lamp placed in series will become incandescent. I could not obtain any evidence that the primary circuit was modified by the presence of the secondary winding, and what was still more important the hyperstatic current did not appear to be at all impaired by the simultaneous passage of the primary current through the body. Thus one is enabled to use both currents at the same time on the same subject, or the D'Arsonval on one and the hyperstatic on another, resulting in a considerable saving of time. (Fig. 5.)

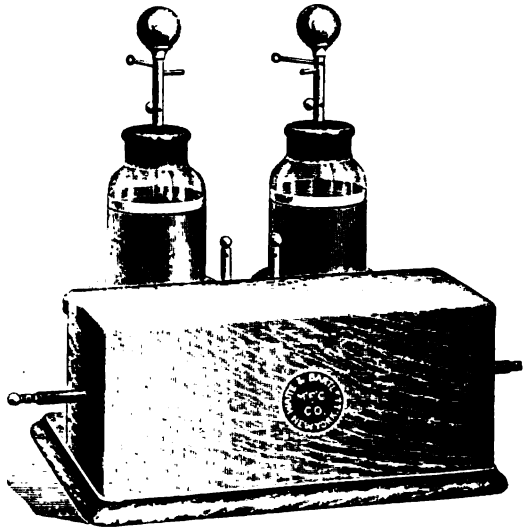

FIG. 5.—The author's improved hyperstatic transformer.

Although both the D'Arsonval and the wave currents exert a powerful influence on metabolism, the *modus operandi* of the two can hardly be the same. The first is a high-frequency current, the second is not. In the first the spark-gap will rarely exceed an inch, and in the second a gap of eight or ten inches is frequently employed. In the first there may be absolutely no sensation while the current is passing—in the second there is a vibratory sensation and the hair stands out from the scalp. After the passage of the D'Arsonval current for ten or fifteen minutes there may be but little change in the feelings of the patient—after the wave current there is generally a feeling of exhilaration and an apparent increase of energy. What changes then occur in the body during the passages of these currents, and in what way are their beneficial effects brought about? To these questions no certain answer can be given. In default of such, it seems reasonable to suppose that the wave current acts through a sort of molecular vibration or cellular massage, while the D'Arsonval may act through the development of heat in the tissues. A current that is capable of bringing the lamp filament to incandescence must of necessity develop more or

*"An Elementary Treatise on Diseases of the Skin," Macmillan & Co., London and New York, 1876.

less heat when traversing bodies that offer a similar high resistance to its passage.

The hasty sketch I have here given of the high-frequency currents is intended simply to attract attention to therapeutic agencies that I consider of high importance, and to encourage further research as to their general utility. The reader who desires to obtain a thorough working knowledge of the D'Arsonval current is earnestly advised to read Denoyés' "Les Courants de Haute Frequence," Paris, 1902; the chapter on "Hochfrequenzströme" (70 pages) contained in Freund's "Grundriss der gesammten Radiotherapie," Berlin, 1903; or Chisholm Williams' "High-frequency Currents in the Treatment of Some Diseases," London, 1903.

## TWO NEW METHODS OF DETERMINING THE DIGESTIVE ACTIVITY OF GASTRIC JUICE.*

By HENRY WALD BETTMANN, M.D.,
AND
J. HENRY SCHROEDER, M.D.,
CINCINNATI, O.

Up to within recent years little attention was paid by clinicians to the digestive activity of gastric juice. During the past decade, however, a number of articles have appeared dealing with this subject. This increase of interest is due to two causes: First, several new methods have been devised which are seemingly simple and accurate enough for clinical purposes; second, it has been discovered that the digestive activity of gastric juice does not always run parallel with the secretion of HCl; or, in other words, that the quantity of pepsin secreted is often independent of the quantity of HCl, and is subject to independent fluctuations.

Some of the older methods of estimating pepsin are accurate, but all are too complicated for clinical purposes.† Only two methods have been used extensively for clinical purposes, those of Mette and Hammerschlag, and all recent work has been done with one of these methods.

The method of Mette, as originally published, is as follows:‡ "Fluid eggwhite is sucked up into a fine glass tube of 1 to 2 mm. lumen, and coagulated therein at a definite temperature (95° C.). The tube is then cut into small pieces, which are placed in 1 or 2 c.c. of the fluid to be investigated. The whole is kept in the thermostat at 37° C. to 38° C., and requires no further watching. Solution of the proteid occurs at the ends of the small glass tubes. After the termination of a certain period the length of the pieces of tube and that of the undigested remains of the proteid columns are measured off with the aid of a mm. scale and a microscope of low magnifying power. The difference gives the length of the digested proteid cylinders in mms. and fractions of a mm. This method leaves nothing to be desired so far as convenience of application and clearness with exactness of results are concerned. Test experiments specially carried out (Dr. Ssamojloff) have convinced us that the digestion of the proteid columns—at least within the first ten hours (employing the fluids which we have to deal with)—is directly proportionate to the length of the period. This was the case even when the fluid possessed its highest digesting power. These experiments did away with the very natural mistrust that the solution of the proteids may proceed at varying rates at different depths of the tubes, dependent on more or less stagnation of the digestive products within the lumen. It may, therefore be accepted that the length in mm. of eggwhite dissolved by the several juices in a certain time gives us an exact relative measure of the digestive power of the fluid. In the researches of Borissow. carried out upon this question in the laboratory of Professor Tarchanoff, the relation which lies at the basis of the connection between the length of the digested column of eggwhite and the pepsin contents of the fluid under investigation came out with perfect clearness. The following is the rule which expresses it, viz., *The quantity of pepsin in the compared fluids is proportionate to the square of the rapidity of digestion, i. e.* to the square of the column (expressed in mm.) which the juices are capable of digesting in the same period of time. An example in figures will make this clear. If one of the fluids digests a column of 2 mm. of proteid, and the other a column of 3 mm., the relative quantity of pepsin in each is not expressed by the figures 2 and 3 respectively, but by the squares of these numbers, *i. e.* by 4 and 9. This rule has, of course, been deduced from comparisons made with numerous artificial solutions of pepsin exactly prepared. Moreover, the result which Dr. Borissow arrived at independently had already been discovered before him by Schütz from polarimetric observation of the amounts of peptone formed during the digestion of eggwhite. This correspondence in the data furnished by different methods affords strong assurance of the correctness of the rule. . . .

"We have still to add that the diameter of the tubes even within wide limits is without importance, and that the white of the hen's egg is of sufficiently constant composition to be employed as a test object for the purpose."

The method of Hammerschlag is carried out as follows: A c. 1 per cent. solution of egg albumen is prepared in the following way: 3.0 g. of albumen ovi sicc. is rubbed up with lukewarm water in a mortar, and then water is added to make the total quantity 150 to 180 c.c. This solution is filtered and officinal HCl is added until the solution contains 3 to 4 per cent. *free* HCl (as tested by titrating with $\frac{n}{10}$ KOH with dimethylamidoazobenzol as indicator). Ten c.c. of this acidified solution is now mixed with 5 c.c. of the gastric juice to be tested and another 10 c.c. is mixed with 5 c.c. of distilled water to serve as a control test. These mixtures are placed in two Esbach tubes, which they exactly fill up to the mark U, and are placed in the thermostat at body temperature for one hour. After one hour they are removed, and Esbach reagent is poured into the tubes up to the mark R. The tubes are inverted several times and then let stand twenty-four hours at ordinary room temperature. The sediment shows the amount of albumen present; in the control tube the original amount of albumen is shown. in the other tube the albumen which has escaped digestion is shown. Thus the proportion of albumen digestion is easily estimated. Hammerschlag says that normal gastric juice digests 80 to 95 per cent. of the albumen in one hour.

Both methods have been used by a number of observers during the past ten years. The necessity for further and more critical work is shown by the variety of the conclusions reached. It is generally conceded that, for clinical purposes,

*Paper read at the sixth annual meeting of the American Gastroenterological Society at Washington.

†A history of these methods is given by Schorlemmer and by Van Valzah-Nisbet.

‡This description is copied verbatim from Thompson's translation from Pawlow, "The Work of the Digestive Glands."

the method of Hammerschlag gives useful though only approximate results. There is no doubt that by this method we are able to determine if a given specimen of gastric juice digests strongly or weakly. Fine discriminations are impossible. According to different authors, the average amount of albumen digested in one hour by normal gastric juices ranges from 50 to 95 per cent. Different averages are given—thus, Schiff 64.6 per cent.; Schüle, 74 per cent.; Kovesi, 50 to 60 per cent.; Hammerschlag, 80 to 95 per cent. A good survey of the literature up to 1902 is found in Schorlemmer. Hammerschlag's method cannot be used for *exact* work for a variety of reasons. In the first place the Esbach tube itself is not an accurate instrument. Two control tubes set up side by side will not always give identical results, even if the tubes have been specially made to order. (The ordinary Esbach tubes on the market show glaring inequalities.) After precipitation the sedimentation of the precipitate is subject to uncontrollable variation. Furthermore, the Esbach reagent precipitates not only the albumen present in the original solution, but also most of the albumoses, and even peptone itself. This reaction necessarily tends to obscure the result.

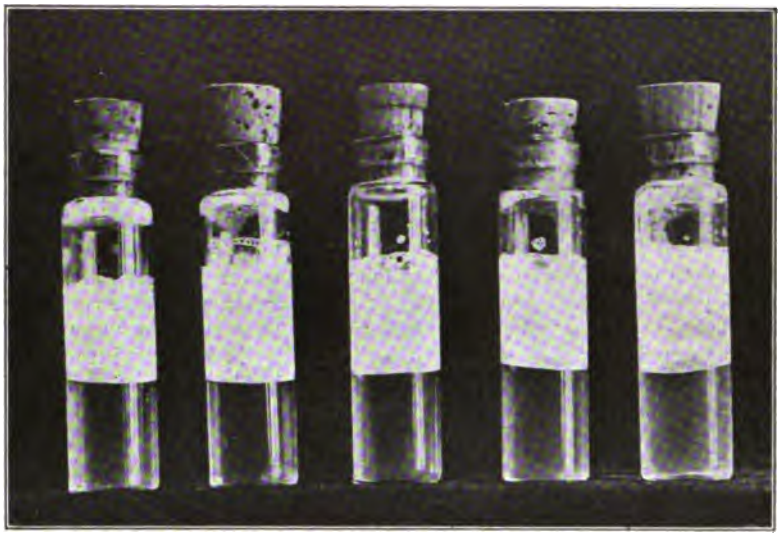

FIG. 1.—Testing Human Gastric Juice for Digestive Power. From left to right: original strength; dilution ½; dilution ¼; dilution 1-16; dilution 1-64. Showing column of foam; the beginning.

We do not believe that the amount of albumen present in the gastric juice after a test breakfast can exercise any appreciable disturbing influence. What effect the difference of free HCl acidity in the different juices has on the results is a problem which has not been worked out conclusively up to the present time. After all of these objections have been weighed it is seen that the Hammerschlag method is useful only until a better method can supplant it. Besides requiring twenty-four hours for its completion, its range of error is from 5 to 20 per cent. or thereabouts. It can be used for clinical estimations, but not for scientific work. As a matter of fact, although nearly ten years have elapsed since its introduction by Hammerschlag, it has never been extensively adopted.

The method of Mette has as yet been little used for clinical purposes. It has been extensively employed in Pawlow's laboratory in his studies of the gastric juice of dogs. It has been thoroughly tested as to its accuracy in determining the pepsin contents of solutions of artificial gastric juice. Roth, working in Ewald's clinic, came to the conclusion that the Mette method is the best and easiest one so far devised for clinical purposes. Schorlemmer, as the result of most painstaking study and experiment, came to the same conclusion. In addition he inferred that there is no parallelism between HCl and pepsin secretion, a conclusion previously arrived at by other observers. The method has also been recommended as the best by Kuttner. The only American author who has used the method of Mette is Jung, and in three-fourths of his cases it gave him results approximately the same as by the Hammerschlag method.

A very recent article by Nirenstein and Schiff has shown that all the work done so far with human gastric juice by the Mette method is unreliable for clinical purposes. These authors have shown that the gastric juice obtained one hour after a test-breakfast contains certain substances which *inhibit* the digestion of the albumen contained in the capillary tubes. They have shown conclusively that by diluting the gastric juice with an equal volume of water or dilute HCl, or even in some cases with four to seven times the volume of water or acid, the digestive activity of the juice is actually increased. The chief inhibiting substances are NaCl and the soluble carbohydrates. It is evident that all previous observations which did not take into account the existence of these inhibiting substances are entirely misleading. Schiff and Nirenstein found that by diluting the gastric juice with fifteen times its volume of a .2-per-cent. solution of HCl the effect of the inhibiting substances is always done away with. They therefore suggest that, in all cases, the test be made with the sixteenth dilution of the gastric juice to be examined.

We have done considerable work with the Mette method, both with gastric juice and with artificial preparations of pepsin and acid. The statements of Schiff and Nirenstein regarding the effect of inhibiting substances are unquestionably correct, and we have repeatedly verified them; and the Mette method, in the form as modified by them, would be admirably adapted for clinical purposes were it not for certain serious objections. The preparation of the tubes of coagulated eggwhite is not easy. Vacuoles appear in many places along the tubes and necessitate the rejection of many pieces. There is at no time a guarantee that the tubes of eggwhite used to test a given gastric juice have just the same resistance to digestion that were possessed by former tubes. Nirenstein and Schiff say that fresh tubes digest too rapidly, and advise waiting until the tubes are three days old. After two weeks they are usually useless. Roth seems to use fresh tubes. Jung found that tubes seven days old were better than those only two days old. Nirenstein and Schiff insist on mixing the thin and thick portions of eggwhite, and using the filtered mixture. Jung advises either the thick or the thin portion, but on no account a mixture. Thus the question of securing uniformity of the albumen column is a problem not yet solved. Reading off or measuring the quantity of albumen which has been digested is usually easy. In strongly digesting gastric juices the line of demarcation between the digested and the undigested portions of the albumen-column is well marked. In weak juices, however, this line becomes less and less well marked, and the

difficulty of reading accurately becomes insurmountable. This is a serious objection to the modification suggested by Nirenstein and Schiff, because the sixteenth dilution of gastric juice digests weakly, the line of demarcation is not always sharp, and a slight unavoidable error in reading must be multiplied by sixteen in order to express the number of pepsin-units according to these authors.

As a result of experimental work done during the past eight months we are able to offer two new methods of determining the digestive activity of gastric juice. These methods differ essentially from each other. One can be performed in a very brief time, and practically without apparatus. It gives results which are accurate, and which fulfil all clinical requirements. The other method requires several hours' time and complicated apparatus, but on the other hand is far more accurate, and, in our estimation, the best method yet devised for very exact clinical or scientific work with human gastric juice.

1. *The Method with Albumen-foam.*—The principles upon which this method rests are as follows: A solution of albumen if shaken will foam. This foam consists of little air bubbles surrounded by thin pellicles or walls of albumen. If a digestive ferment is mixed with the foam the albumen will be digested and the foam will disappear. *Other things being equal, the rapidity with which the foam disappears is proportionate to the amount of digestive ferment added.* This simple principle gives us a ready method of determining the digestive activity of any fluid, *e. g.* gastric or pancreatic juice.

For testing the peptic activity of gastric juice we use an acidified solution of albumen, which is prepared according to a method given in detail below: The solution contains about 1 per cent. of albumen ovi sicc. and .2 per cent. free HCl in water. The only apparatus required is one or more 2-drachm bottles known commercially as "homeopathic vials." Two c.c. of the albumen solution is placed in such a vial, and to it is added 1 c.c. of the fluid containing pepsin (or the gastric juice). The bottle is corked and then thoroughly agitated. For the sake of uniformity we give fifty violent shakes, which gives a column of foam about as high as the fluid on which it rests. In testing solutions rich in pepsin more shaking is required to produce a column of foam of that height.

The bottle is then placed in an incubator at 37° to 40° C. (preferably an incubator with a glass door, if such be available), or placed in a glass of warm water, or simply held in the hand. We have found it convenient to place the bottle inside a test tube filled with warm water, and to stand the latter in a glass of warm water. We have made many experiments with normal and abnormal gastric juices, and with artificial gastric juice containing .4 per cent. pepsin in .2 per cent. free HCl. As a result of these observations, we can state with assurance that *the time required for the foam to disappear is an accurate test of the amount of pepsin present in the solution.*

With the above artificial gastric juice the foam disappears in eight minutes. In normal gastric juice the time is ten minutes. Regarding the disappearance of the foam, for practical purposes it is convenient to call the foam dissolved when the upper surface of the albumen solution is clear of foam and only a slight rim of foam adheres to the sides of the bottle. The law of Borissow and Schütz fortunately gives us a ready means of testing the accuracy of any method for the determination of peptic activity. According to this law (discovered by these observers independently of each other, and by different methods), the rapidity of digestion is as the square root of the pepsin concentration, *e. g.* four times the pepsin strength will give twice the digestive activity; nine times the pepsin strength will give three times the digestive activity.

We have made repeated tests with artificial and human gastric juice, and their second, fourth, eighth, sixteenth, thirty-second, and sixty-fourth dilutions, and have found, with the exception mentioned below, that the time of the disappearance of the foam is in conformity with the law of Borissow and Schütz. A table is appended giving the result of these observations. We believe that this table demonstrates the practical value of the method, and shows that it is sufficiently accurate to meet all clinical requirements. We have, moreover, compared the results obtained by this method and by our more accurate method given below, and found that the results approximate each other closely.

FIG. 2.—Showing the test-vials of figure 1 after ten minutes' digestion. Foam of test with original gastric juice has just disappeared (10 minutes). Dilution ½ and ¼ are following. Dilution 1-16 and 1-64 unchanged.

TABLE I.

The foam method conforms to the law of Borissow and Shütz with artificial gastric juice.

THE FIGURES REPRESENT THE TIME IN MINUTES REQUIRED FOR THE DISAPPEARANCE OF THE FOAM.

| CONCENTRATION | EXPERIMENT I | EXPERIMENT II | EXPERIMENT III | EXPERIMENT IV | THEORETICAL FIGURE |
|---|---|---|---|---|---|
| 1 | 8 | 8 | 9 | 8 | 8 |
| ½ | 12 | 11 | 12 | 11 | 11.2 |
| ¼ | 16 | 15 | 19 | 17 | 16 |
| 1/16 | 33 | 30 | 36 | 32 | 32 |
| 1/32 | 42 | 42 | 42 | 42 | 44.8 |
| 1/64 | 60 | 60 | 60 | 62 | 64 |

We have found that many human gastric juices, by virtue of some physical property not yet discovered, cause in their original strength a too rapid breaking down of the foam out of proportion to their pepsin strength. In order to eliminate any error which might arise from this source, we advise diluting the gastric juice before testing it. As a diluting fluid we use three times the volume of a .2-per-cent. solution of HCl. This dilution does away with another source of error, viz., different acidity of different gastric juices. By diluting any

gastric juice, whatever its HCl content, with three times its volume of a .2-per-cent. solution of HCl, we, in all cases, bring its acidity within the normal range. The dilution has an additional virtue that it enables us to make the test with very minute quantities of gastric juice; ½ c.c. is a sufficient quantity to determine accurately the pepsin contents of a given gastric juice.

We may now describe the test as follows: A small quantity of the gastric juice is diluted with three times its volume of a .2-per-cent. solution of HCl; 1 c.c. of the diluted gastric juice is placed in a homœopathic vial, and to it is added 2 c.c. of a 1 per cent. solution of egg-albumen containing .2 per cent. free HCl. The vial is thoroughly agitated (fifty violent shakes usually suffice) until a column of foam about 2 cm. high is formed. The vial is now placed in the incubator at 37° C.—40° C., or in water kept at that temperature, and the time required to clear the surface of foam is noted. In the one-fourth dilution of a normal case the foam will disappear in twenty minutes. If this time is divided by two it will represent the time required by the original undiluted gastric juice, and from this time the actual pepsin strength of the gastric juice can be calculated. For example: if a juice which we are testing when properly diluted requires forty minutes for the disappearance of the foam, we may say that the undiluted juice would dissolve the foam in twenty minutes, *i. e.* that it has one-half the digested activity of normal gastric juice, or contains one-fourth as much pepsin. A diluted juice which requires eighty minutes has one-fourth the digestive activity of human gastric juice, and contains one-sixteenth of the normal pepsin. In all cases requiring one hour or more we advise repeating the test with the undiluted gastric juice (whose acidity can be modified if required by adding one drop of a proper strength HCl), and the peptic activity can be estimated directly by comparison with the time for undiluted gastric juice, ten minutes.

In order to save time and reduce the test to its simplest, the tests can be made as a routine procedure with undiluted gastric juice of proper acidity. In case the juice shows unusually rapid digestion (four to six minutes), it is well to repeat the test with the one-fourth dilution as above described.

This test is a very useful qualitative test for pepsin in gastric juice, and in many respects is superior to the fibrin method ordinarily used.

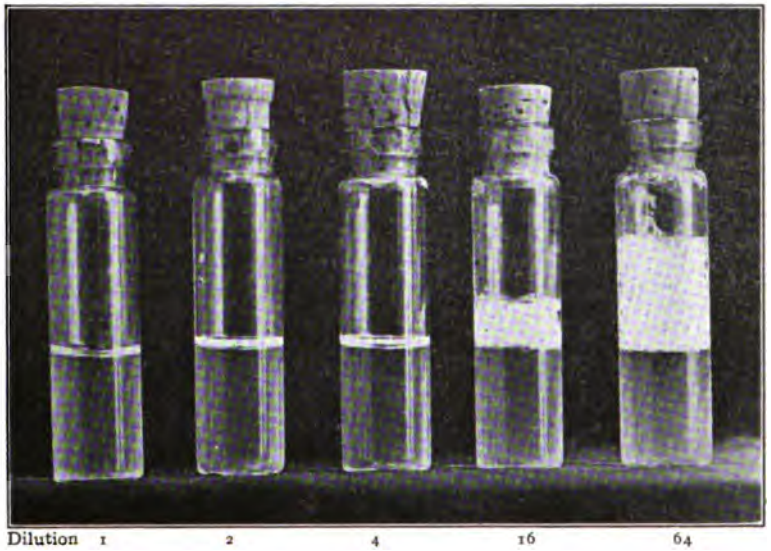

FIG. 3.—Showing the same vials after twenty-one minutes' digestion. Foam with original gastric juice disappeared in 10 minutes; dilution ½ in 15 minutes; dilution ¼ in 21 minutes. Dilution 1-16 shows disintegration and should disappear in 40 minutes, and dilution 1-64 in 80 minutes

The accompanying illustrations illustrate the foam-method graphically and also prove its practical accuracy. (See accompanying photographs.)

*The Centrifugal Method.*—The inaccuracies of the Hammerschlag method led us to seek for a new method which, in the first place, would prove really accurate, both for scientific and for clinical work; and which, in the second place, could be carried out in a shorter time. The principle underlying Hammerschlag's method we accepted as correct. In order to hasten the process and render its results more accurate, we called to our aid the centrifugal machine. Instead of waiting twenty-four hours for a precipitate to settle more or less accurately, by means of the centrifugal machine we were enabled to get accurate results in two hours. The centrifugal process of testing with accuracy the albumen contents of any fluid presents many problems which it required months of experiment to solve. The requirements of the method are these: (1) An albumen solution which will keep, and which will give uniform reactions (precipitates). (2) A precipitant which will precipitate all the albumen but none of the peptone. (3) A centrifugal machine uniform enough in its workings to give equal sediment under similar conditions. (4) Centrifugal tubes graduated accurately and finely enough to allow accurate readings.

1. An albumen solution which meets all requirements can be made as follows: 1.0 g. of albumen ovi sicc. is placed in a mortar and 2 c.c. of distilled water is added under constant trituration until the albumen is apparently dissolved. To this solution HCl (U. S. P.) is added drop by drop, with constant stirring until, with dimethylamidoazobenzol as an indicator, the HCl appears free in the solution. Water is now added to bring the volume up to 100 c.c. The amount of free HCl is determined by titration with $\frac{n}{10}$ KOH and sufficient HCl is added to make the amount of free HCl 0.2 per cent. This solution is now placed in the incubator at 37° C. over night, to swell. This "ripening" of the solution is exceedingly important. After removal from the incubator a drop of chloroform is added to preserve the solution* (this is not essential), and the solution is let stand in order to settle. The solution thus prepared undergoes no alteration and gives uniform results for many weeks.

In seeking a suitable precipitant, we experimented with a number of reagents. One of the objections to the Esbach reagent is that it precipitates peptone. We hunted for a reagent which would precipitate albumen and all the products of imperfect digestion (albumoses) but which would have no effect on peptone. With such a precipitant the end figure represents *the percentage of albumen which has been completely digested*, and there can be no confusion in interpreting the results. After many experiments we selected a 10 per cent. aqueous solution of trichloracetic acid as the most suitable precipitant. This solution precipitates albumen, the globulins, and both

*The small amount of chloroform does not in any way interfere with the action of pepsin. If desired it can easily be driven off by mildly heating the albumen solution.

the primary and secondary albumoses, but it has no effect on peptone. Moreover, the precipitate obtained with this reagent is not spongy. It packs easily, and in the centrifugal machine gives an upper level which can easily be read off. Heat, nitric acid, potassium ferrocyanide, and picric acid, all have shortcomings which render them either inapplicable or undesirable for centrifugal work.

Regarding the centrifugal apparatus itself, we found that either a high grade electrical centrifuge or one of the modern water-power centrifugal machines gives highly satisfactory results. The water-power centrifuge used by us makes 1,200–1,500 revolutions per minute, according to the varying water pressure. We have found by comparing sediments that it gives as reliable results as the more expensive electrical machines.

In our earlier work we made the mistake of not allowing enough time to the actual process of centrifugalization. We soon discovered, however, that the smaller the precipitate the sooner did the packing become complete, and unless sufficient time were allowed for the larger precipitate (that in the control tube) to become densely packed the results were misleading. After many trials we found out that two hours sufficed in all cases (with our machine) to give thoroughly packed sediments.

The centrifugal tubes were especially prepared for us by Mr. Emil Greiner, New York. The ordinary "Purdy tubes" on the market are not accurate enough for scientific purposes, and work done with them may result in errors up to 10 per cent., or in some cases even more. Mr. Greiner, upon our suggestion, selected "Purdy tubes" which were uniform as to their shape, and subdivided the lower centimeter into tenths, and these again into fifths, so that the lower cubic centimeter was subdivided into fifty equal parts.

We have given the above description in detail, because all centrifugal work, in order to give accurate and uniform results, must be invariably done in a uniform way, and with carefully prepared and tested apparatus.

To those who have ever worked with albumen solutions, one question will present itself at the outset, viz., *Is the method of estimating albumen by the volume of centrifugalized sediment an accurate method?*

Purdy has answered the question in the affirmative for albumen in urine, and we can answer in the affirmative for our solution of eggwhite. We present the following table to illustrate the very great accuracy of the centrifugal method, the largest error in any experiment being 3 per cent.:

TABLE II.

Illustrating the accuracy of the centrifugal method with carefully measured albumen solutions.

| SEDIMENT IN CONTROL TUBE IN ⅕ CMM. | STRENGTH OF SOLUTION | SEDIMENT IN TESTING TUBE | INDICATING AN ALBUMEN SOLUTION OF |
|---|---|---|---|
| | Original solution | | 100 per cent. |
| 25 | 10 per cent. | 3 | 12 " |
| 25 | 20 " | 5 | 20 " |
| 25 | 30 " | 7.5 | 30 " |
| 24 | 40 " | 9.6 | 40 " |
| 25 | 50 " | 13 | 52 " |
| 25 | 60 " | 15 | 60 " |
| 20 | 70 " | 14 | 70 " |
| 24 | 80 " | 18.5 | 77 " |
| 24 | 90 " | 21.5 | 89.5 " |

In every instance the control tube was filled with 10 c.c. of our original albumen solution, and 5 c.c. of trichloracetic acid was added. The variation of the sediment between 20 and 25 cubic millimeter-fifths was due to the centrifugalization being performed at different times of day and night when the water pressure in the mains varied greatly. Experiment 8 was done late at night when the water pressure was unusually great. In the second tube were placed consecutively 10, 20, 30, 40, 50, 60, 70, 80, 90 per cent. dilutions of the original solution, and the same precipitant was used. The table shows that the precipitate in the diluted solutions in every instance gives an accurate index of the strength of the solution.

The accurate results shown in Table II taken in conjunction with experiments reported above enable us now to say definitely: If two tubes containing the same quantity of a uniform albumen solution are placed in an incubator at 37° C. to 40° C., and if to one tube 5 c.c. of gastric juice is added, and to the other (the control tube) 5 c.c. of a 0.2-per-cent. solution HCl; and if digestion is allowed to continue a certain length of time, and if at the end of this time the solutions are precipitated with a 10-per-cent. solution of trichloracetic acid and centrifugalized—then *the difference in the volume of the two precipitates represents the quantity of albumen which has been changed into peptone*, and this can be expressed in percentage. The sediment in the control tube is an index of the original quantity of albumen used.

As stated above, the law of Borissow and Schütz gives us an ever-ready means of testing the accuracy of any method of estimating albumen, and we have on numerous occasions subjected our method to that test, both with artificial and with human gastric juice. It is important to recognize at the outset, however, that *the law of Borissow and Schütz is not applicable to concentrated solutions of pepsin, but only to solutions of moderate strength.* Julius Schütz estimated that the law is applicable only when not more than one-half of the original albumen is digested. Borissow tested the correctness of the law by the Mette method, and found it to be applicable only to dilute solutions of pepsin. Samojloff examined dogs' gastric juice, and found that it would have to be diluted at least four times to come within the workings of the law. Nirenstein and Schiff discovered that the law of Borissow and Schütz applies to pure pepsin solutions used in the Mette method only when the original solution is not strong enough to digest more than 3.9 mm. of albumen. This limitation of the law is a serious obstacle to any method yet devised for estimating pepsin in human gastric juice, except the foam-method above described. *Normal gastric juice obtained one hour after a test-breakfast is too strong to come within the workings of the law, i.e.* we are not able to estimate the exact pepsin content of normal human gastric juice by testing its digestive activity. This will be made clear by the following tables, which illustrate experiments made to test Borissow's law with artificial and human gastric juice. (See Tables Nos. III and IV.) Examined by the centrifugal method:

Showing the limits of Borissow and Schütz Law.

We can avoid the confusion which thus arises by again resorting to the expedient of working with diluted gastric juice.

A one-fourth dilution of artificial gastric juice will digest 50 per cent. to 60 per cent. of the albumen in the test solution in seventy minutes.

A one-fourth dilution of normal gastric juice will also digest between 50 and 60 per cent. of the albumen in seventy minutes.

With these norms or standards in view we can best test the pepsin strength of gastric juice by using the one-fourth dilution.

The steps of the process may now be briefly recapitulated as follows: The gastric juice to be tested is diluted with three times its volume of a .2 per cent. solution of HCl. This diluted juice and the standard albumen solution are placed in the incubator about fifteen minutes in order to be warmed to body temperature. In each of two test tubes are placed 10 c.c. of the standard acidified albumen solution. To one tube 5 c.c. of the diluted gastric juice is added, to the other (the control tube) 5 c.c. of a .2 per cent. solution of HCl. These tubes are then placed in the incubator at 37° to 40° C. for exactly seventy minutes. At the end of that time they are removed, and 10 c.c. are taken from each tube and placed in the centrifugal tubes graduated to .02 c.c. To each tube is added 5 c.c. of a 10-per-cent. solution of trichloracetic acid, and after inverting the tubes several times they are placed in a high-speed centrifugal machine and centrifugalized two hours. At the end of this time the tubes are removed, and the volume of sediment measured. The sediment in the control tube will be an index of the original albumen strength of the standard solution. The sediment in the second tube will be less, if digestion has taken place, the difference in the two sediments representing the proportion of albumen which has been transformed into peptone.†

## A CASE OF NEUROFIBROMA OF THE SKIN AND LARGE NERVE TRUNKS IN WHICH THERE DEVELOPED A LARGE SPINDLE-CELLED SARCOMA BENEATH THE BODY OF THE SCAPULA.*

By H. W. AUSTIN, M.D.,
DETROIT, MICH.
SURGEON U. S. PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

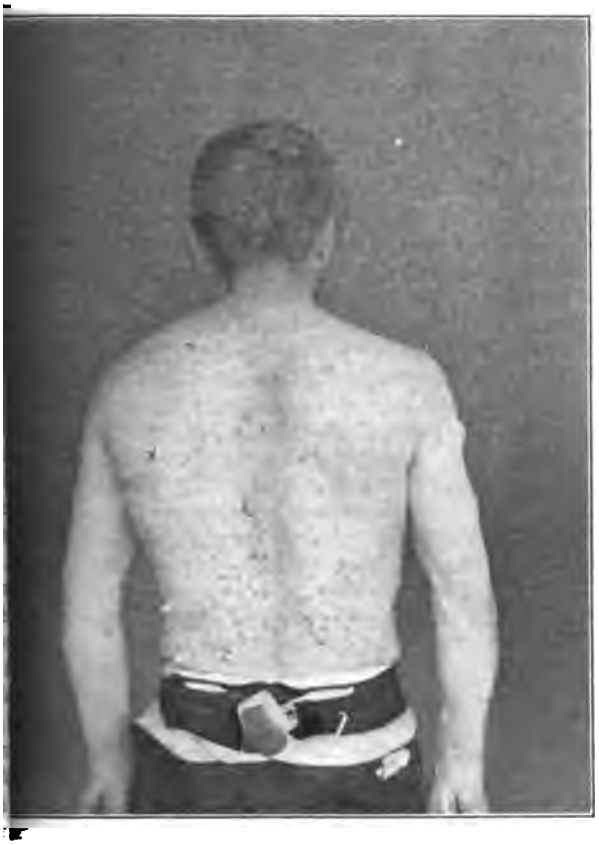
I have to report a case of multiple fibroids of the skin (molluscum fibrosum), of multiple fibroids of the large nerve trunks from the brachial plexus of the left side, and of a large spindle-celled sarcoma, arising from beneath the body of the left scapula, all developing at the same time in one person.

A typical case of molluscum fibrosum is rarely seen, and such a case having also multiple fibroids of the nerves and sarcomata is, so far as I am able to determine from the literature of this disease, unique. The question of interest which engages the mind of the surgeon is this: is there a causal relation between the fibroids of the skin, and nerves, and of the fibrosarcoma: or is their occurrence at the same time simply accidental? The case which I have to report was shown at a general meeting of the Wayne County Medical Society several months ago, on the day when the patient was first seen by the writer, but at that time nothing was known of the sarcoma, and the nature of the tumor upon the arm had not been determined, although it was thought to be a fibroid of the musculospiral nerve, which proved to be correct. The patient, Chas. A., a fully developed man of medium intelligence, aged forty-six years, nativity Portland, Me., was admitted to the U. S. Marine Hospital, Detroit, December 16, 1902, with a diagnosis of molluscum fibrosum. The following history was recorded: He has been a sailor all his life, and has sailed around the world twice, stopping in China, India, Japan, and Australia. During the past five years he has been a "sailor man" upon the steamers of the great lakes. With the exception of an attack of rheumatism about four years ago, his general health has been good. He arrived at the port of New York from London in 1893, and was vaccinated at quarantine, which vaccination was followed by a slight eruption, probably vaccinal, which disappeared in a few days. Soon after this eruption he noticed small nodular growths of the skin of the body and extremities. They have been slowly increasing in size since that time, and are present are seen on every part of the body, but are larger and more numerous upon the trunk, especially upon the back and abdomen. They range in size from a pea to a large English walnut, and number several hundred. On palpation they do not feel unlike soft lipomata, and resemble somewhat tumors of this character within or beneath the skin. These skin tumors have never given him pain, although some of the larger ones have caused him some inconvenience and annoyance in dressing. His application for hospital relief was on account of a tumor located just above the external condyle of the left humerus. This tumor, which is a deep-seated tumor, about the size of a pullet's egg, was first observed by the patient about four years ago, but caused him no trouble until a few months prior to his application for relief at the hospital. During his last two months' service on the vessel, he had suffered much pain from this tumor, which was increasing in size, and anodynes were required to afford relief. There was slight paralysis of the left hand, it being much weaker than formerly. Quinine, arsenic, and one of the synthetic analgesics were given, and application of the *x*-ray made over the nerve tumor and over certain regions of the skin, where the skin tumors were numerous, but no benefit was derived from the treatment. The pain in the tumor of the left arm increased, and pain in and around the left shoulder became very severe. An examination revealed considerable enlargement about the shoulder-joint, in the scapular region, and on the chest wall near the shoulder-joint. On December 22, 1902, the pain in the arm having become unendurable, I performed an operation for the removal of the tumor of the arm. Ether was administered, and an incision about three inches in length was made along the course of the musculospiral nerve just above the elbow. A tumor of this nerve, about the size of an egg, was found. A longitudinal incision into the tumor was made, but it was found impossible to differentiate or separate the nerve fibers from the growth. The nerve was stretched, the tumor removed, and the divided ends of the nerve brought together and carefully sutured, and the wound closed. The wound healed without suppuration, and the pain in the arm ceased. Pain continued in and about the shoulder however, and the swelling increased rapidly. I became suspicious that a malignant growth had appeared beneath the body of the scapula, and finding a small tumor on the chest wall which could be felt by pushing the hand well up in the axilla, and beneath the pectoral muscle, I decided to remove and examine it. The patient was given ether, and the tumor removed, which proved to be a fibrous tumor of the anterior

*Read before the Surgical Section of the Wayne County Medical Society, Detroit, Mich.

†Complete literary references are found in the later articles published in the current numbers of the *Archiv für Verdanngskrankheiten*. See especially Vol. VIII, parts 3 to 6.

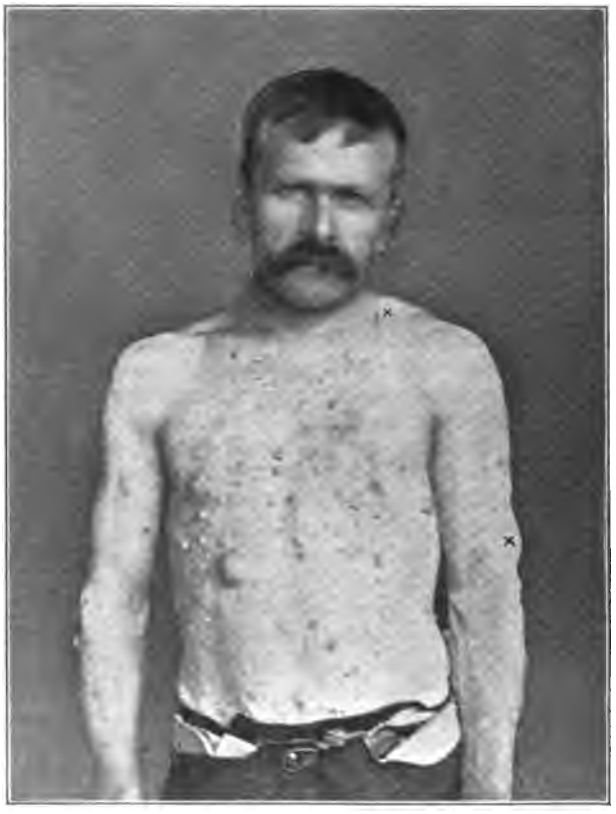
thoracic nerve, resembling the one removed from the musculospiral. The tumor was about the size of an English walnut. I examined both nerve tumors under the microscope, and thought them to be fibroids; they were then sent to the Service Laboratory at Washington, where they were



examined and pronounced fibroids. The specimens are well mounted and show the character of the tumors beautifully. The following description of the specimens was made by the Director of the Laboratory, Dr. Rosenau: "The specimens were imbedded in paraffin, sectioned and stained with hæmalin and eosin and with Mallory's connective tissue stain. The sections show many spindle-shaped nuclei, surrounded by fibrillating protoplasm. Beneath the fibers in some places is seen a homogeneous myxomatous-like substance, with round nuclear-like bodies. In some portions the tissue is more dense than in others, and seems to be distinctly collected into lobular-like masses. Newly-formed blood vessels, with distinct walls apart from the tumor mass, are seen in the section. Each specimen seemed to have a distinct capsule. Diagnosis: Soft fibromata, or molluscum fibrosum."

As neither of the nerve tumors appeared to be malignant in character, it was thought that the tumor developing beneath the scapula might be benign, although its rapid development was evidence to the contrary. The *x*-ray had been tried without effect, and the patient was again suffering intense pain in the scapular region, and also in the left arm from the hand to the shoulder. An operation for removal was decided upon, and the patient was informed of the risk of the operation, and of the possible return of the disease. He insisted upon an operation, saying that it was impossible for him to endure the pain longer. On January 29, 1903, the patient was prepared for an operation. An anæsthetic was given, and with the assistance of Drs. Mathewson and Granbery, I operated for the removal of the tumor. An incision was made along the superior border of the scapula, and an attempt made to remove the tumor through this incision, which was but partially successful, as the tumor extended beneath the entire body, and into the axilla. A second incision was made along the inner or vertebral border of the scapula, a part of the rhomboideus minor being preserved. After control of the hemorrhage, the tumor was dissected out, principally with the hand and handle of the scalpel. The immense cavity left by its removal, extending from the corocoid process to the inferior angle ot the scapula was packed firmly with sterile gauze, the wound dressed and a firm bandage applied. The tumor which appeared fibrous, but rather easily torn, was of a yellowish color, containing few blood vessels and a cyst holding about two ounces of an amber-colored fluid. The tumor seemed to be divided near the center of the scapula transversely, although it is probable that the division was not complete. The lower part of the tumor weighed one pound and the upper part with the cyst about eight ounces. Specimens of this tumor were also examined at the laboratory of the service at Washington, stained and mounted. The following is the description of the microscopical examination of the tumor:

"Specimens of the tumor were imbedded, and after being sectioned, stained in various ways. The section shows a mass of spindle-shaped cells with long nuclei. Small blood vessels are seen, the walls of which are composed simply of an endothelial lining of the tumor mass,there being practically no independent vessel wall. The diagnosis of small spindle-cell sarcoma was readily made. There are two specimens, one stained with eosin and hæmalum, and the other stained by Mallory's connective tissue stain. By using oil immersion with the latter specimen you will observe, where the section was at right angle to the direction of the



fibers, that the connective tissue fibers and the intracellular substance penetrates between the individual cells." It was thought that the tumor originated in the periosteum of the under surface of the scapula, near the suprascapula notch, as the bone was there denuded of periosteum and necrosed

for some distance along its under surface. The patient, although suffering considerably from shock due to extensive mutilation, rallied quickly, and in a few days the upper wound closed, the lower wound only partially.

The patient suffered less pain for a week or two, but the tumor soon appeared again, and grew with wonderful rapidity. Daily application of the *x*-ray seemed to have no influence upon the growth nor upon the pain. The erysipelas toxin treatment was considered, but it was believed to be impracticable, owing to the weakened condition of the patient. The patient rapidly grew weaker as the tumor increased in size, and died March 20, 1903, fifty-one days after the removal of the sarcomatous tumor.

At the necropsy it was found that the musculospiral nerve, which had been resected and stitched, had united, but another tumor, fusiform and about two inches long and five-eights of an inch in diameter, had formed. A tumor, about the size of an orange, was found on the long thoracic nerve, and several small nerves from the brachial plexus had small bulbs in their course. A large, soft fibrous tumor, weighing about three pounds, extending from the under surface of the body of the scapula, through the axilla of the left side to the clavicle in front, involving in its mass the brachial plexus of nerves, was found. A cyst, containing 200 c.c. of yellowish translucent fiuid, was situated in the supra-scapula region. Metastasis had taken place, and large nodules, resembling the tumor, were found at the base of the right lung, and in the diaphragm, just beneath the right lung, and just above the liver, which organ was not involved. One small nodule, about the size of a chestnut, was attached to the sixth rib outside of the pleura upon the left side. The lymphatic glands appeared to be normal.

It is not my intention to discuss the various theories of the pathogenesis of neoplasms, or to explain or support any one of the many theories of the method of extension of malignant tumors, or of the conversion of benign tumors into malignant tumors, but simply to invite attention to the possible relation which may exist between the skin, the nerve, and the sarcomatous tumor of the scapula.

Kaposi refers to certain rare cases which might be classed as molluscum fibrosum, sac-like humid thickings of the skin which have resulted from congenital connective tissue or vascular moles which, in some instances, owing to their anatomical relations with the neurilemma of the large and the smaller nerve trunks and branches in the skin, and to the presence of plexiform neuromata that might be interpreted as fibromata of the nerves. These sometimes give rise to the most violent neuralgic pains. In the case presented, is there reason to believe that the genesis of the fibroids of the skin, and of the fibroids of the nerves is the same, and is there a causal relation between the fibroids of the nerves and the fibrous sarcoma lying in close proximity? The microscope showed the character of the tumors to be distinct; one a pure fibroid, and the other a spindle-celled sarcoma, yet the nerve tumors and the sarcoma developed in close proximity—in fact, in juxtaposition. Soft warts, pigmented patches upon the skin, moles, nævi, and other congenital defects of the skin are frequently seen formed among these fibrous tumors upon the body. This has been remarked by many observers. Bowen and Besnier claim that soft warts and nævi are closely related to molluscum fibrosum, and it may be difficult to distinguish molluscum from soft warts. That the analogy between the two affections is so close that differentiation is not a matter of great importance. The frequent development of sarcomatous tumors from such congenital defects of the skin is well known. Goldman and Garrá state that multiple sarcomata of the nerves arise from defective development of the nerve sheath. Williams, in giving the histogenesis of fibrous sarcoma, says that many chronic forms of fibrosarcoma contain so much fibrous tissue as to obscure their sarcomatous elements. According to Virchow and Kaposi, molluscum fibrosum starts from the connective tissue layer around the fat lobules, but, according to von Recklinghausen, these growths are neurofibroma, that they start from the perineurium of the subcutaneous nerve branches, and grow upward into the skin. This latter view has the support of Unna and Garrá. He claims that the neurofibrous connective tissue in the larger nodules is sharply bounded from the surrounding skin. That the neoplasm contains a conspicuous number of mast cells which are regularly distributed throughout its area. Unna claims there is a widely distributed myxomatous change in the connective tissue cells, peculiar to these neurofibroma. Hebra and Virchow believe the disease to be hereditary in some cases.

The claim of Recklinghausen that these fibrous skin tumors, moluscum fibrosum, are neurofibromata is, I believe, true, and the occurrence of multiple fibroids of the large nerves in this case of molluscum fibrosum shows the same pathological tendency in the nerve trunks and in the nerve periphera. The rapid growing malignant tumor may have originated in a neurofibroma of the upper subscapular nerve—that is, a small neurofibroma may have assumed a malignant form or undergone sarcomatous degeneration.

---

## SOME NOTES ON A DIET OF BREAD AND FRUIT, AND ITS EFFECTS ON HIGH BLOOD-PRESSURE, DROPSY, AND OBESITY.

By ALEXANDER HAIG, M.A. and M.D. OXON., F.R.C.P., LONDON.
PHYSICIAN TO THE METROPOLITAN HOSPITAL AND TO THE ROYAL HOSPITAL FOR WOMEN AND CHILDREN.

It may be said roughly that those who live on bread and fruit alone require to eat each day about 2 ounces of bread for each 10 pounds in their body weight. This is as near as one can get with a rough statement, and if a considerable proportion of the bread so used is either toasted bread or biscuit, which are 10 per cent. foods, and if, further, the weight which is calculated is not all muscle, which has to be nourished, but is partly fat, this calculation will often not be very far from the mark. On this allowance a person who weighs 140 pounds will require to eat 28 ounces of breadstuffs a day, and of this we may say that 21 ounces may be taken as breadstuffs and 7 ounces may be taken as dried fruits, even though these latter are not of the same nourishment value as bread. Any loss over the dried fruits will probably be made up in the small quantity of milk which is taken with the breadstuffs when they are made into puddings. Such a day's food would divide into three meals as follows: Seven ounces of breadstuffs a meal and 2 to 3 ounces of dried fruit per meal. To this may be added, if desired, a small quantity of potatoe or other vegetable, or of any fresh fruit that is in season. A meal of this kind would be in detail 2 ounces of toasted bread, 2 ounces of biscuit, 3 ounces of pudding, 2 to 3 ounces of dried fruit, and a little vegetable and fresh fruit as before mentioned. Those who desire to have an almost uncooked diet can take these things exactly as they are here stated. There is in this diet very little cooking, except the vegetables

and the pudding, which last, by the way, should be firm and solid, more like cake than pudding, and be of such substance that it almost requires a knife to cut it; but those who wish for more employment for their cooks can modify this diet so as to give them almost any required amount of work, and they can also, if they like, spend almost any amount of money on the elaboration of such a diet. The first course of such a meal may then be a vegetable soup made with milk. A little only of this would be taken, and it would be used as the sauce to some part of the toasted bread and biscuit. Next course, a savory dish of some kind made with vegetables along with rice, maccaroni, cheese, and other substances used as flavorings. This, or some part of this, might be taken along with a little vegetable as a sauce to the remainder of the toasted bread and biscuits. Next course—sweets, tarts, and cooked fruits—may be elaborated to almost any extent, but these again should be used only in small quantity and as sauces to the breadstuff pudding, which is the main staple of the next course. After this there may follow a more or less elaborate savory cheese dish, with which again should be eaten further quantities of breadstuffs, the cheese dish being the sauce to these meals. The dried fruits also may be eaten along with the pudding course, and last we come to the dried fruits or preserved fruits, and various elaborations of fruits and sweets, which can, if necessary, be worked up to any extent. It seems to me that it is one of the great advantages of this diet that it lends itself so splendidly to the use of those who on the one hand, might wish for an absolutely simply, and to a large extent, uncooked diet, to be obtained, carried and eaten elsewhere, and, on the other, almost equally well to the use of those who wish for a great amount of cooking and the elaborate work of highly-trained modern artists.

The chief advantage of a bread and fruit diet is seen in the collæmic or high-blood-pressure group of uric-acid food poisonings. Such used to be called diseases, and were reckoned under the names of headache, epilepsy, depression, neuralgia, asthma, Bright's disease, cerebral hemorrhage, cardiac failure, angina, dropsy, and obesity. The great point in the relief of these troubles is the lowering of the blood-pressure, which it is obviously impossible to bring about on a diet of milk, which contains much fluid. By cutting down the fluids to the smallest amount compatible with comfort, and feeding on breadstuffs, dried fruit and fresh fruit, or, as a modification in certain cases, on dried fruits, nuts and fresh fruit, a blood-pressure of 150–160 mm. of mercury can be reduced in a week or two to 120 mm. of mercury, with a correspondingly large improvement in all the forms of food poisoning above mentioned. Thus headaches may be diminished to one-half of their previous frequency and severity, fits similarly diminish to one-half, depression, neuralgia and asthma diminish, or even more or less completely disappear, and in Bright's disease dropsy is removed and the heart has a chance of recovering, while obesity slowly and steadily diminishes as the diet is continued; then as cerebral hemorrhage is due to high blood-pressure, to lower it as quickly as possible is the most obvious indication for treatment. This is, of course, the mere mechanical result of the diminution of fluid, and with every diminution of fluid there must of necessity follow a diminution of the blood-pressure. Later on freedom from uric-acid poisoning, which this diet also brings about, has its effect, and the improved condition increases still further and becomes permanent. We have heard a great deal about the washing-out plan by copious drinking of fluid, which does great harm in all the above conditions of raised blood-pressure, and does not increase the excretion of uric acid in the least, as I have pointed out in "Uric Acid," sixth edition, page 885. But the almost marvelous results that can be produced by a dry diet in all these troubles associated with slow capillary reflux and high blood-pressure and more or less dropsy, seem to be known by few or none. Nothing, in my opinion, really cures these conditions but the removal of the uric-acid-containing foods to which they are due, but while pure diet is slowly bringing the body and its circulation to more natural conditions and to freedom from food poisoning, the diminution of the fluids to the lowest level compatible with life, which is possible on this bread and fruit form of the uric-acid-free diet will produce an improvement almost at once, which is often well on to half way to cure. I make bold to say that there is no case of headache or epilepsy associated with high blood-pressure (and the vast majority of idiopathic headaches and epilepsies are met with in this association) which would not yield very markedly to such a fall of blood-pressure as is produced, for instance, by the Tufnell diet in the treatment of aneurysm, and a very similar fall of blood-pressure can be produced by the dry diet of which I am speaking. Indeed, a bread and fruit diet will lower blood-pressure more than the Tufnell diet, and might often, with advantage, be substituted for it. The Tufnell diet lowers blood-pressure entirely mechanically, but bread and fruit diet does this, and in addition also lowers blood-pressure by shutting out unnecessary uric acid. The 'washing-out' plan in such conditions is almost the height of folly, and only those will believe in the improvement that can be made by the dry diet who have witnessed its results in some of these cases. As it is the mechanical result of diminished fluids, it can be produced, as in the Tufnell treatment, by a diet which is not free from uric acid; but, when the trouble, as in the cases above-mentioned, is originally due to uric-acid poisoning further obvious advantage can be obtained by leaving the poison out.

In many of these high blood-pressure troubles much good may also be done by a temporary, but complete abstention, from both food and fluid, as this will produce, in from twelve to twenty-four hours (varying with the amount of fluid in the body to begin with), a fall of from 20 to 40 mm. of mercury in the blood-pressure; and this will make the difference in many cases between a severe headache and a slight one, or between a slight headache and none, or again between a series of severe fits and one or two slight ones; and if such patients have been constantly kept on a small allowance of fluids a correspondingly greater and more prompt effect can be produced by this complete abstention from food and fluid.

Certainly in no case with a blood-pressure of 180–200 mm. of mercury will the patient incur the least danger if both food and fluid are withheld for from twelve to twenty-four or thirty-six hours; but the blood-pressure can be watched and a little food and fluid given (best in the form of toast or biscuit with a little fresh fruit) so soon as the pressure has fallen nearly to normal, say 120 mm. of mercury.

---

**A Prize for Dr. Roux.**—The French Academy of Medicine has awarded the prize of 100,000 francs ($20,000) for the most remarkable scientific work to Dr. Roux of the Pasteur Institute. Dr. Roux accepted the prize, but requested that he be allowed to devote the amount to investigations at the Pasteur Institute.

# HALLUX VALGUS.

By JOHN G. SHELDON, M.D.,
TELLURIDE, COLO.

It has been suggested that the term Hallex Valgus be used instead of Hallux Valgus. Of course, Hallex is Latin and will stand criticism; but Hallux is a good word and has served a good purpose. The term Hallux Valgus is short and definite, and has been in use for a considerable period of time. I cannot see that much is to be gained by using Hallex instead of Hallux. It makes little difference which term is used if the importance of the condition is recognized.

I have reason to believe—from reading and from observing cases—that hallux valgus has not received the consideration from surgeons that it deserves. I find that the condition is quite common; that many times it is very annoying; that sometimes it completely disables the patient and that comparatively few cases have been subjected to surgical treatment. To me, hallux valgus has become at once an interesting and a valuable subject. A few cases came to me desiring surgical relief for the condition; many patients, suffering from hallux valgus, came to be operated for other conditions. These cases almost invariably submitted to the operation for hallux valgus at the time of undergoing operation for other conditions. By using these methods I have operated a number of cases. The results have been satisfactory both to the patients and to myself.

Very little has been written on the etiology of hallux valgus. It is generally stated that the condition is due to the wearing of improperly fitting shoes which turn the great toes outward. As the deformity increases, secondary changes occur. Dawbarn says that a subluxation of the joint exists and that changes in the head of the metatarsal bone rarely occur. Most writers, however, agree that in some cases distinct bony changes are found. A painful, tender, and sometimes inflamed and suppurating bursa, over the head of the first metatarsal bone, not uncommonly complicates the condition.

I believe: (*a*) that an improperly fitting shoe is never the sole cause of hallux valgus; (*b*) that hallux valgus, in the great majority of cases, occurs in feet so formed as to predispose to the condition; (*c*) that the extensor proprius hallucis muscle plays a most important rôle in causing and aggravating the condition, and (*d*) that osseous changes, in the inner side of the distal end of the first metatarsal bone, are commonly found in severe cases.

It is impossible to determine the exact relation of the shoe to hallux valgus, or to prove that the shoe does or does not cause the condition. I firmly believe that a pointed shoe will aggravate a case of hallux valgus, or even make manifest the condition in a foot of a certain shape; but I am just as firm in the belief that there are certain feet in which a hallux valgus could not be developed no matter what sort of shoe should be worn. In my opinion, the shoe bears the same relation to hallux valgus as does the corset to nephroptosis. In support of my statement, I wish to say that I have seen people wear pointed and tightly fitting shoes for three or four years without developing hallux valgus, and that I have seen some of the worst cases of hallux valgus in persons who have worn only wooden shoes.

All of the cases of hallux valgus, that I have seen, have occurred in patients whose feet were of one type: instep high; arch of the foot well formed; the extensor tendons of the great toes prominent at the metatarsophalangeal joint; the first phalanx of the toes extended and the distal phalanges flexed. I have never seen a case of hallux valgus occurring in a patient afflicted with flat-foot.

I believe that the extensor proprius hallucis muscle is a structure that is prominent in producing and in aggravating the disease. The following facts support this statement: (1) The muscle is stronger than the muscles that antagonize it. (2) It is always found tense in cases of hallux valgus. (3) Its insertion is so situated that it abducts the great toe. (4) Slight abduction of the great toe places the tendon in such a position that the abducting power of the muscle is increased. (5) I have had six cases that presented the symptoms of beginning hallux valgus, in which I lengthened the extensor tendons of the great toe, and the condition did not develop. (6) The deformity does not tend to recur after the tendons have been lengthened or divided.

I have operated on at least thirty cases of hallux valgus. In all of these there was a subluxation of the first metatarsophalangeal joint as observed by Dawbarn, and also some change on the inner side of the distal end of the first metatarsal bone. In some of the cases there was marked bony hypertrophy. I have never seen any changes present in the phalanx, neither have I seen abnormal conditions present in the outer side of the distal end of the first metatarsal bone.

*Treatment.*—Mechanical appliances have been devised and recommended in the treatment of hallux valgus. I have seen them tried in three cases without success. I believe they are practically useless in advanced cases.

Retaining the toe in proper position with plaster of Paris has been recommended; and, in some cases, the insertion of the tendon of the extensor proprius hallucis has been transplanted to the inner side of the great toe to aid in preventing abduction. I have had no experience with these methods, but should think them to be inadvisable in cases with subluxation or with osseous deformity.

Resection of the metatarsophalangeal joint is unnecessary and will be dismissed without discussion.

Barker and Reverdin recommended osteotomy of the metatarsal. I have had no experience with this operation.

Weir advises incision of the inner part of the capsule of the joint, with resection of the inner part of the head of the metatarsal. Good results are reported from this procedure.

R. H. M. Dawbarn operates as follows: A constrictor is applied to the extremity. The joint is exposed by making a flap, the convexity being upward and outward. The head of the metatarsal bone is resected with a Gigli saw without injuring the tendons or sesamoid bones. The space occupied by the resected bone fills with blood and heals by the blood-clot process. The toe is held in proper position with a planter splint, and with plaster of Paris, which is applied to the knee. The constrictor is not removed until the dressing is completed. The cast is removed in four weeks. Dr. Dawbarn reports excellent results from this operation in over fifty cases. A painless, not tender and movable joint is obtained. He ignores the bursa unless it is suppurating. Then he excises it and does not perform the radical operation till healing is complete.

In six cases of beginning hallux valgus, I made an incision over the tendon of the extensor proprius hallucis; split the tendons of the extensor proprius hallucis and extensor brevis digitorum muscles a distance of one inch; divided one portion of each tendon at the upper end of the split and the re-

maining portion at the opposite end, thus dividing he tendons in such a manner that they could be engthened two inches without complete separation f their fibers. No attempt was made to suture he divided tendons. The toe was held in proper osition with a planter splint and adhesive plaster. fter about ten days the dressings were removed. he toe remained in proper position and the power f extension was present. The results in these cases ere satisfactory. The first case operated was xamined thirty-two weeks after the operation. t this time the patient had complete control of he toe and there was no tendency toward develop- ent of hallux valgus. I should recommend this rocedure only in mild cases.

I have operated on twelve cases according to the ethod recommended by Dr. Dawbarn. The esults were quite satisfactory in ten of them. n one infection occurred. The joint was stiff but as not painful or tender. In another patient, the ound healing was perfect, but the joint remained ender and was painful at times. In all of these ases the toe was somewhat shortened.

The procedure that I recommend in all well- narked cases of hallux valgus is as follows: If an nfected bursa is present, it requires removal and omplete healing of the wound before performing he radical operation.

*Radical Operation.*—The skin incision is made, ac- ording to Dawbarn, except in cases with a tender ursa. In these cases, excise the bursa and as uch of the overlying skin as is compatible with omplete closure of the wound. The next step is to free the inner portion of the distal end of the first metatarsal with a chisel or periosteotome. The inner one-half or two-thirds of the head of the bone is then removed with bone forceps. The outer one-third or one-half of the articular surface of the metatarsal, and the phalanx, are not dis- turbed. The extensor tendons of the great toe are then divided in the manner described in the foregoing. The fascia and ligaments are then drawn together with catgut and the skin approxi- mated with silkworm gut. The toe is held in proper position with a planter splint and adhesive plaster. I usually apply a constrictor before operating; but without constriction the hemorrhage is slight.

I have operated upon twelve cases by this method and in all of them the result has been perfect in three or four weeks—the toe being in proper position and not shortened; the joint freely movable and not painful or tender. One toe became infected, but this produced no bad effects.

The advantages of this method are:

A movable joint is assured.

There is no shortening of the great toe.

The deformity is completely corrected.

If the bone is affected, the abnormal part is removed.

The space resulting from the removal of the bone heals by the blood-clot process.

The extensor tendons are so lengthened that they do not tend to reproduce the deformity.

Moderate infection would doubtless not prevent the obtaining of a good result.

---

**Education in Great Britain.**—Mr. Balfour, in a speech delivered a short time ago in Manchester, drew the follow- ing disheartening picture of the state of education in Great Britain: "The existing educational system of this country is chaotic, is ineffectual, is utterly behind the age, makes us the laughing stock of every advanced nation in Europe and America, puts us behind, not only our American cousins, but the German and the Frenchman and the Italian.

**The Rôle of the "Ball-Valve" in the Etiology of Appendicitis.**—C. Van Zwalenburg considers that in many cases there is, preceding obstruction to the exit of secretions and inflammatory products from the appendix, an increased nitra-clonic pressure which overdistends the appendix, and by its recoil closes the valve. The presence of a concretion is not essential. Any firm mass behind any narrowing of the lumen or sharp bend in the same way may act as a ball-valve. The mucous membrane resting upon the hard, resisting, fibromuscular wall is easily compressed and its blood vessels and those ramifying in the submucosa are thus compressed or obliterated by the hydraulic pressure within the appendix. The ever-present pathogenic bacteria are quick to take advantage of any diminution of the fighting forces of the tissues, and immediately plant their colonies upon them, thus producing infection and inflammation. If it is true then that in many cases appendicitis is in the beginning a simple mechanical derangement, often a strangulation, the importance of immediate operation can hardly be overestimated.—*Southern California Practitioner.*

**Report of a Case of Decapsulation of the Kidney (Edebohls' Operation) for Chronic Parenchymatous Nephritis.**—James Tyson and Charles H. Frazier report the case of a girl of nine years suffering with chronic parenchymatous nephritis. At the first operation the right kidney was decapsulated. The child was œdematous from head to foot and the peritoneal cavity was distended to its utmost with ascitic fluid. One week after the operation the anasarca had disappeared. In six days a total of 362 ounces of urine were voided. The maximum was reached on the fourth day. From this time the daily quantity decreased to an amount varying from thirty-five to forty ounces. Casts and albumin never entirely disappeared in the six weeks following operation. Two months after the first operation the left kidney was decapsulated. Two weeks later there was just a trace of albumin and a few hyaline casts, but when the patient was allowed to get up, they again appeared. Both operations were borne unusually well. Although the writer had been skeptical about this operation, he believes from his experience with this case, that one cannot justifiably disregard such results obtained in a patient so desperately sick and without the slightest prospects of recovery. He declares that in the future he shall not hesitate to perform this operation in a patient in whom all attempts at alleviating the condition by every means other than operation had failed, and in which the patient was daily losing ground and death was imminent, provided it was reasonable to assume that the patient would survive the immediate effects of the operation.—*University of Pennsylvania Medical Bulletin.*

**Report on Treatment of Plague by Large Doses of Carbolic Acid.**—J. C. Thomson used carbolic acid in a series of over 200 cases of plague in Kennedy Town Hospital. He gave 144 grains of carbolic acid daily, divided into two hourly doses of 12 grains each, and administered in a mixture flavored with syrup of orange and chloroform water, in some cases over long periods. One patient took over 2,500 grains of pure carbolic acid before his blood was free from plague bacilli. Although carbolic acid poisoning was expected to appear often, it was practically unknown. In a few cases carboluria developed, but the omission of one or two doses was generally sufficient to clear the urine and permit resumption of the remedy in full doses. In certain cases dyspeptic symptoms occurred, but in these greater dilution of the mixture with water overcame this obstacle. The writer considers carbolic acid in large doses the most hopeful means of treating plague thus far at their disposal in Hongkong. Bell's method for the diagnosis of plague is most valuable. Although of great service in the treatment of plague, carbolic acid is by no means a specific remedy. The writer hopes for the next epidemic season to have the production locally of a curative serum for the treatment of plague.—*The Journal of Tropical Medicine.*

## THE STATUS OF THE NAVY SURGEON.

A CONSIDERABLE amount of dissatisfaction exists—and has existed for a long time—among the medical officers of the navy with regard to the manner in which their brother officers of the line arrogate to themselves all authority. The captain of a man-of-war is an autocrat. Officers of an inferior rank have their well-defined duties, and exercise a certain amount of authority, while the navy surgeon, whose position is one of great responsibility, possesses no power whatever, not even over his own patients. The captain of a war vessel can, if he so wills, take the surgeon's patients off the "sick list" and compel them to do the regular work of the ship. This action may be taken in direct opposition to the advice of the medical man. That is to say, the captain, who presumably knows nothing of medicine or surgery, is allowed, by virtue of his office, to override the opinion of a legally qualified medical practitioner.

This state of affairs, anomalous and absurd as it may seem at first thought, is doubtless justified to a great extent by the circumstances of the case. A battleship is first, and last a fighting machine, and her officers and crew are trained and placed in her for the purpose of carrying out this intention in the most effective manner possible. In time of war all else must be subordinated to the exigencies of the situation. The captain's duty is to destroy or cripple the enemy in any way open to him—in fact, to win at any cost. No humanitarian scruples must be allowed to imperil the successful accomplishment of this object, and although it may seem brutal, the wounded and sick must, if necessary, be sacrificed to the honor of the country and flag. In time of peace discipline has to be maintained at a very high level, and it has been decided that this result can best be reached by investing all authority in the captain. His word is law, and if he be determined to carry out his will or caprice in face of the advice of a man whose trained knowledge qualifies him in this particular matter to speak with more authority, he can do so, and no one may say him nay. As to whether a navy surgeon, although on board ship, should not be allowed to use his own judgment, and to have more or less free action in his own especial province, is a question which cannot be settled offhand.

Doubtless, as a rule, the captain of a ship does not interfere with the surgeon, but the fact remains that he can if he desires. Time has cast its halo of sanctity over the present mode of procedure, and it has become crystallized by custom. It is not only at sea, however, that the line officer shows himself, sensitively jealous of his rights and privileges.

A case described in the *Army and Navy Journal* of June 27 exhibits this disposition to resent the very slightest attempted infringement thereof, in a striking manner. The acting chief of the Bureau of Medicine and Surgery, in an official communication referred to the senior officer at a naval hospital as "in command." Captain Thomas of the *Franklin* immediately took umbrage at this expression, and inquired of the Navy Department if there had been any recent change in the naval regulations, as he was of the opinion that both the law and the regulations prohibited officers of the naval staff corps from exercising "command," and that the senior medical officer at a hospital is "in charge."

Surgeon-General Rixey was appealed to for his opinion upon the matter, and concluded from a consideration of 1 Section 7, Chapter 413, Statutes at Large, Fifty-fifth Congress, of the Act of March 3, 1899, entitled "An Act to Reorganize and Increase the Efficiency of the Personnel of the Navy and Marine Corps of the United States," and from other apparently cogent facts which point the same way, that there seems to be no reason why the term "command" should be denied to naval medical officers any more than any other word which means control. Judge-Advocate General Lemly, on the other hand, held that the senior medical officer had not the right to the term "in command," and the Secretary of the Navy, who was of the same opinion, expressed himself upon the matter as follows: "The question raised herein seems to be one of form and not of substance. The powers of a medical officer in charge of a hospital are neither increased by describing him as 'in command,' nor diminished by describing him as 'in charge.' Both expressions signify effective control, and the powers and duties of a medical officer are to be ascertained otherwise than by examining the description of his authority. The Judge-Advocate General points out that in Articles 1135 to 1155, Navy Regulations, dealing with the duty of medical officers at hospitals, the expression used is 'in charge' and not 'in command.' This is notably the case in Article 1137, which describes the responsibility, duty, and authority of the senior medical officer. No reason is perceived for changing the designation used in the regulations and sanctioned by long-established practice. The opinion of the Judge-Advocate General is approved, and the bureau will inform the Bureau of Medicine and Surgery and the commanding officer of the *Franklin* of the department's decision in this matter."

The whole dispute as to the right of a senior medical officer of a hospital to term himself as "in command" might seem to a layman a somewhat trivial matter. Upon the question, however, hinges an important point of principle, the status of the naval surgeon ashore. At sea he has no authority, but that is no sufficient reason, that when at the head of a hospital on land he should not be permitted to use the term "in command," even if it does not add an iota to his authority. It would seem, as matters now stand, that a physician in the navy is to use a homely phrase, "neither fish, fowl, nor good red herring." He is an officer who has to obey but cannot command, and even in his sphere of work is subject to the caprices of a commanding officer. His status should be more accurately defined than it is at present, or it might be well if he were made entirely independent of military organization.

## CONCERNING CANCER.

THE *London Hospital* for October 3 contains a long article by Mr. D'Arcy Power, F.R.C.S., on cancer. The writer considers the disease from several aspects. He refers to that period when little was known of medical science as it is now understood, and when what would at the present time be denominated as crude ideas regarding the origin of cancer were prevalent. He terms this period the pre-scientific era. Mr. Power next treats of the scientific era of investigation, and draws attention to the fact that the late Sir James Paget was the first to suggest that if a microorganism of cancer existed, it might rather be of an animal than of a vegetable type—a protozoon and not a protophyte. The infective theory of its origin is briefly dealt with, and it is stated that the infective hypothesis is valuable as a stimulus to original work, but it has rather drawn away the thoughts from other fields which may prove even more fruitful, for as yet, except in Jensen's experiments, no results of any permanent value appear to have been ascertained.

With regard to the distribution of cancer, Dr. Lloyd Jones is quoted as follows: "These are the points upon which, in each case, several of the most trustworthy authors are agreed: (1) That cancer picks out certain districts, and that there are areas of immunity and cancerous areas; (2) that immune areas may be close beside cancerous areas; (3) that malignant disease is most common along the banks of rivers or streams; (4) that elevated districts or plateaus are more free from cancer, while low-lying districts carry more liability to its inroads; (5) that isolated cancer houses often occur near to woods, orchards, or forests of firs; (6) that people living upon flooded and clay districts and retentive soils are especially liable to its ravages; (7) that limestone districts are comparatively free from cancer, but do not confer absolute immunity; (8) that cancer may be disseminated by means of water, that it depends upon the presence of decaying animal or vegetable matter or upon sewage; (9) lastly the suggestion is thrown out by some observers that insects may play a part in the dissemination of malignant disease.

The research work on cancer of nowadays is aptly termed by Mr. Power the era of coöperation. As he truly remarks, it is only recently that there has arisen a decided tendency to work in association and under the guidance of some central authority. The initiative in organized work was taken by Germany, where a representative commission was formed by the selection of members from different countries to inquire into the cause of cancer. A similar commission was formed in the United States under the title of "The Cancer Commission of the Surgical Department of the Harvard Medical School." Dr. Power pays a high compliment to this school for the manner in which it has conducted and is conducting this work. The MEDICAL RECORD has on more than one occasion commented editorially upon the work of the Harvard Medical School as regards its investigations into the cause of cancer, and the results arising therefrom. In England a cancer research fund was formed in 1902, and by the first year's report just issued, it is shown that the investigations are to be carried on upon thoroughly scientific lines, and that some good work has been already accomplished.

Dr. Bashford, the General Superintendent of the British Cancer Research Fund, has recently published a short contribution to the literature of the disease entitled "The Problems of Cancer." The gist of the argument in this work is that much may be effected in the way of solving the problem of the origin of cancer by studying more closely the occurrence of malignant disease in animals. "Indeed," says Dr. Bashford, "an examination of malignant disease in animals may prove to be of the greatest value, for the length of the human life-cycle has been a great impediment to the solution of many problems which can be easily investigated in short-lived animals." Further, he says, "Old age in the domestic animals is attained at fourteen to twenty years or less, it is obvious, therefore, that identical manifestations first presenting themselves in any number in mankind after forty years of age, and in the common domestic animals at fourteen to twenty years, must pass through the latent non-manifest stages in a much shorter period in the latter. It may be that this latent period will be found to be in strict proportion to the duration of life, and in this case it will be different and definite for each species in the same way as in the period of gestation."

Dr. Power concludes his able dissertation upon cancer by saying "that although the only treatment at the present time which holds out any prospect of cure of cancer is a radical operation, yet we are slowly accumulating evidence to show that other methods of treatment will be as available and may be even more effective in the near future. It has been known for a long time that undoubted cancers sometimes dwindle instead of growing. The removal of the ovaries in women has undoubtedly in some cases an influence in arresting the growth of cancer of the breast. The injection of an appropriate serum, there is reason to believe, has actually cured cases of fungating cancer which were thought to be beyond the reach of surgical interference. In each the rationale of the cure has been the same—cessation of the growth in the epithelial cells with increased formation of fibrous tissue. These are the lines of treatment which must be followed in the future and which will probably lead us to an explanation of the cause of cancer, and may, at the same time, afford a rational cure. But at present all treatment except that by direct removal is in an experimental stage; the other methods are only tried in desperate cases, their results at present are too uncertain to allow of the formulation of rules, and their use is consequently purely empirical."

The MEDICAL RECORD, some time ago, strongly urged the advisability of coöperation between scientific men of different countries engaged in cancer research. The great difficulty in the way of successfully carrying out this plan is the personal one. Few men are so altruistic as to deny themselves the fame and glory arising from a great scientific discovery. Emulation, too, acts as a spur to most workers, but at the same time coöperation might be so arranged that the honor of an important discovery might be placed where it is justly due. In the solving of the problem of the origin of cancer, there would be honor enough to be divided amongst many.

### Syphilis in Its Ethical Relations.

In the first instance, it must be granted that while there is prostitution, venereal diseases will exist, and, secondly, that, as it is impossible to do away with prostitution, so must venereal diseases continue. The aim, then, of all rational social reformers is to devise a system whereby the spread of syphilis and gonorrhœa shall be checked—in a word, to endeavor to keep prostitutes as free from disease as possible. The schemes conceived and set on foot to attain this object have been multifarious, but success has not been nearly reached. The system in force on the European continent of licensing houses of prostitution, and of placing them under police and medical supervision, has been tested for a considerable period, but apparently has been found wanting. The *American Medical Review of Reviews*, September 25, contains an article on the subject contributed by the late Dr. S. Seabury Jones. The writer reviews the methods in vogue on the European Continent for checking venereal diseases, and showed that, on the whole, failure has been the outcome. Numerous statistics are given in support of this contention. For instance, in 1843, there were 235 licensed houses in Paris; in 1888 only 67; in 1887, 927 licensed prostitutes and 3,755 unlicensed. In St. Petersburg, in 1872, there were 220 licensed houses. In 1890 only 67. In 1891 there were in St. Petersburg 608 licensed prostitutes, and 2,319 others. The percentage of prostitutes suffering from venereal disease was, in Paris, from 1878 to 1887, in licensed houses 25 per cent., 12 per cent. of whom was suffering from syphilis. In other houses, 15 per cent. and 7 per cent.

In Brussels, 1887 to 1889, 50 per cent. were suffering from venereal disease; 25 per cent. from syphilis, against 33 per cent. and 9 per cent. In St. Petersburg, 56 per cent. suffering from venereal disease; 33 per cent. from syphilis as against 19 per cent. and 12 per cent. Lyons, 85 per cent. suffering from venereal disease, 4 per cent. in ordinary houses. Rotterdam, 25 per cent. against 10 per cent., "So that," said Dr. Jones, "in houses under observation, the percentage of syphilis under regulation was larger than in other houses." He further said: "It has been found from statistics that those living in controlled houses are oftener in the hospitals, 90 per cent. of them have entered in the hospitals as against 22.4 per cent. of outside prostitutes. Bergh of Copenhagen has remarked "that the prostitutes who live in controlled houses are less careful of their bodies, as they feel less personal responsibility." The saying of Le Bert, in 1876, to the effect "that the controlled houses are, will, and must be, in spite of all man can do, even daily examinations, probable centers of venereal infection as well as the high schools of vice."

Dr. Jones, after having pointed out the inherent and radical defects of all other measures which have been initiated to lessen the prevalence of venereal diseases, gave his opinion as to the best means of reaching this end, as follows: First and foremost, the education of the public as to the nature of the disease, the method of its communication, and the symptoms which indicate its existence and its onset. If the prostitutes themselves shall be thoroughly instructed in the symptoms of the disease, so that they may be able by inspection to detect the disease in themselves or in those who visit them, a great deal will have been done to prevent its spread. If those indulging in impure intercourse shall be thoroughly instructed in the proper antiseptic measures to be undertaken on such occasions when they have rendered themselves liable to contamination, a great deal more will have been done, and when, finally, hospitals and clinics shall be established in which those suffering from venereal disease —especially women— will receive careful and humane treatment, so that, instead of being repelled by harshness they will be drawn to seek help and curative treatment without fear of punishment, a great deal more will have been done in this direction.

---

### Statistics of London.

The report of the London County Council during the year 1902-1903 has just been published, and supplies much useful information. The population of the administrative county of London is stated to be 4,536,541 persons, an increase of 308,224 persons in ten years. What is called "Greater London" covers a larger area than the administrative county, and contains a population of 6,581,402 persons, showing an increase of 947,596 persons in the same period. Of the total population, the females exceeded the males by 252,371, showing the presence of 1,118 females to every thousand males, as against 1,116 females to every 1,000 at the census of 1891. Of the total population 135,377 persons are of foreign birth. Of these, 38,117 are Russians, and Germans come next, with 27,427; Poland is responsible for 15,420, France for 11,224, and Italy for 10,889, with the difference that Italian women over twenty greatly outnumbered the men—a condition which does not obtain to so great an extent with other nationalities. Holland, Austria, and Hungary, and Switzerland also send contingents, but in comparatively small numbers.

The health of London—according to the report—is eminently satisfactory, the death rate for 1901 having been only 17.1 per 1,000 as compared with 18.6 in the preceding year; and as is well known, there has since been a further diminution. The number of deaths said to have been hastened by privation was 35 in 1901, against 53 in 1900; and the deaths from accidents in the London streets were 49 against 56 in 1900. The statistics of habitual drunkenness present some really peculiar features, as out of 99 cases known to the police, one man and 89 women were apprehended. The fact, whatever may be the explanation, is extraordinary, and may, perhaps, be attributed to the well-known misleading nature of figures.

The *London Times* commenting editorially upon the council's report, gives some interesting statistics with regard to the tenement question in London. On March 31, 1902, the Council had completed 2,950 tenements, accommodating 15,060 persons, and had in progress further tenements to accommodate 66,432 persons. The total number completed or planned, amounted to 15,198 tenements, for the accommodation of 89,054 persons. Besides these dwellings, there are in addition, those erected by the Peabody Fund, the Guinness Trust, and other associations or companies for the attainment of similar objects; and it appears that the work of these associations is collectively greater than that of the Council, the associations having completed 19,899 tenements containing 50,155 rooms and accommodating 100,310 persons.

The baths and wash-houses provided for the benefit of the tenement dwellers do not seem to have met with much favor at their hands. In almost every district where these conveniences have been erected they have failed of being self-supporting, in some instances the deficit on them being considerable. The poor of London manifestly do not believe in John Wesley's dictum that "Cleanliness is next to godliness."

A perusal of the above figures must convince all that London is making strenuous efforts to care for the physical and moral well-being of her poor. New York is as yet far behind London as regards good tenements for her working population, and model lodging houses. There is ample scope for the labors of philanthropists in the down-town districts of New York, in these respects, and the rebuilding of certain sections would be a service of the greatest possible value not only to the inhabitants thereof but to the population of the entire city. The force of the statement that insanitary dwellings are a menace to the whole community cannot be too strongly insisted upon.

---

### The British Commission on the War in South Africa.

With remarkable unanimity British journals of whatever shade of politics, and lay and medical alike, unite in severely scoring the War Office for the lethargy it displayed in preparing for war. The army seems to have been unready for a campaign in nearly every particular, the medical department not excepted. From a consideration of the matter it would appear that red tape and a steadfast adherence to antiquated methods were the chief reasons for the state of chaos that ensued upon the declaration of war. The medical department did as well as could be expected under the adverse circumstances, but as in all other branches of the service, it was so hampered by the lack of men and equipment that it was doomed to at least partial failure. The *Lancet* of September 26 concludes a review of the commissioners' report, and makes some pungent criticisms on the careless unpreparedness of the British Government revealed therein. Referring to the medical department, the writer in the *Lancet* says: "As to the skill of the army surgeons and the quality of the equipment, the views expressed by the witnesses were somewhat divergent, but the testimony to the personal zeal and devotion of the medical officers was practically unanimous. The want of sufficient training in military surgery and medicine was pointed out, and the situation in respect to this was compared unfavorably with the methods employed in some other European countries—notably in Germany. . . . There is one fundamental difficulty in the professional training of our medical officers which has been largely overcome by an essentially military power like that of Germany. It is to make such training, as far as possible, of a practical character. Actual experience in the application of medical and surgical methods, such as falls to the lot of members of the medical and surgical staffs and to the resident surgeons and physicians of civil hospitals, has, it is needless to say, a value of its own, compared with which other acquisitions of knowledge are of relatively insignificant importance to the individual or to the State. Medical officers should unquestionably be encouraged to make themselves asquainted with the methods of army medical administration, hygiene, and equipment of other countries, and we look forward to the time when leave will be granted to them for this purpose and for taking out special courses of instruction both in this country and on the continent." There can be no doubt that it is an error of the first magnitude, not to keep an army medical department in the best of working order, both as regards men and equipment. Whatever the size of an army may be it should have its full compliment of surgeons. These men should have every advantage afforded them to learn their duties thoroughly, and should not be compelled to train themselves in time of war. It is a trite but true remark that being prepared for war is a long step toward victory. Few nations will attack another nation which is well prepared for war, and it must be borne in mind that the medical department is an essential part of a military organization, and one which for humane reasons alone should be kept up to the highest standard.

---

### The Immunization of Animals to the Bacillus Typhosus.

The efforts which have been put forth of late to produce a reliable anti-typhoid serum cannot be said to have been crowned with success. There is no agreement as to the efficacy of Professor Wright's method of anti-typhoid inoculation, although the weight of evidence would appear to warrant the belief that this mode of protection against an attack of typhoid fever is not to be depended upon. With regard to the surpassing importance of discovering some prophylactic agent which would prevent—if only to a limited extent—the prevalence of this disease, there is no need to insist. In time of war the death rate would be immensely decreased if it were not for the occurrence of typhoid fever. In almost every war which has taken place within the past fifty years this malady has been the cause of the greatest mortality.

Dr. W. Vernon Shaw, Wellcome Physiological Research Laboratories, writing in the *Lancet*, October 3, points out that in the case of typhoid fever it is especially difficult to produce an effective anti-serum, for the reasons that the organism is attacked as a whole, though the brunt of the attack falls on the tissues first invaded—*i.e.* the lymph follicles of the intestine, and further the reactions of the organism invaded by the bacillus typhosus are not well defined.

Another practical difficulty in the production of active immunity to the typhoid bacillus is the separation or production of a soluble toxin. Rowland and MacFadyen claim to have proved the presence of intercellular toxins in the bacillus typhosus. Their method was to grind up agar cultures of the bacillus, and so obtain a soluble toxin. With this view Professor Welsh agrees. Mallory goes further, and is of the opinion that the proliferation of the lymphoid tissues of the intestine, the mesenteric glands, and the spleen pulp is caused by the specific action of the typhoid toxin. Welsh —according to Dr. Shaw—is in accord with this idea, and thinks that the proliferation of these cells is partly compensatory and partly defensive.

Dr. Shaw's experiments were undertaken to show: (1) the virulence of the particular bacillus used; (2) the effect of normal horse plasma on bouillon cultures; (3) the immunization of a horse to the bacillus typhosus; (4) the value of the serum from such a horse; (5) the bactericidal power of normal blood compared with that from an immunized horse on the bacillus typhosus.

The conclusions reached as the result of these experiments were as follows: (1) The best method of obtaining a toxin is by the digestion of the bacilli. (2) This product is toxic. (3) This product can excite a reaction in susceptible animals, during which they develop immunity to the injection of living typhoid bacilli, and the serum from such an animal can protect another animal against typhoid infection. (4) The injection intravenously of living typhoid bacilli may result in the production of a "negative phase" of resistance.

### The Artificial Feeding of Children.

In the *Lancet* of September 19 is published an address by Dr. Robert Hutchison, dealing with this perennially interesting subject. So great is the concern manifested in the matter—and rightly so—that the literature bearing upon the best methods of bringing up infants by means of artificial food is voluminous to a degree. The writer of the article referred to, doubts the soundness of the prevailing belief that the artificial feeding of the very young is attended with almost insuperable difficulties. Of course he does not deny that there are babies, the artificial feeding of whom taxes the ingenuity of the most experienced practitioner, but at the same time contends that the majority of infants can be nourished in most satisfactory manner upon artificial food.

The fault, in his opinion, of the frequent cases of non-success in this endeavor almost invariably lies in the lack of a definite plan of campaign. Dr. Hutchison says, "in order to succeed it is necessary to follow definite lines, beginning with a mixture selected on rational grounds as suited to the digestive powers of the particular child with whom we have to deal, and if that fails after a proper trial—and the balance is the only arbiter of success—passing on to a mixture which we know to be more easily digested, and from that, if need be, to one which is more easily digested still."

It goes without saying that cow's milk is regarded by the writer as the sheet-anchor in the artificial feeding of children. But raw cow's milk not being suitable on account of the indigestibility of its casein, such milk must be diluted so as to provide a nourishing pabulum for the infant.

Dr. Hutchison holds that diluted cow's milk, condensed milk, and peptonized milk are the most suitable artificial foods for children, and their respective value is represented by the order in which they are here placed. He recapitulates his arguments as follows: "(1) The first essential in the artificial feeding of infants is to have a definite plan upon which to go, and to avoid haphazard procedures. (2) Diluted cow's milk, condensed milk, and peptonized milk may be regarded as the positive, comparative and superlative of digestibility, respectively, and should be tried in that order until the digestive power of the child is suited, due regard being paid to details of administration. (3) Periodic weighing of the child is the only test of the success or failure of the food selected. (4) In cases in which even peptonised milk fails to give good results, great benefit often follows the administration of gray powder, even in cases in which there is no reason to suspect a syphilitic taint. (5) In spite of all care in the use of the above methods, there remains a residuum of cases in which progressive wasting persists, many of these seem to be babies who are unable to digest the casein of cow's milk in any form. (6) In such a case one should try to procure a wet-nurse for the child, and failing that, one must eliminate casein from the diet by making whey the basis of the feeding mixture. (7) The use of a patent food as the sole article of diet for a baby is rarely, if ever, necessary, so long as cow's milk can be obtained either fresh or condensed. (8) If a child is unable to digest cow's milk, it is often worth while to try the effect of adding a little starchy food to the diet, even at an early age, for inability to digest milk appears to be sometimes accompanied by an unusual capacity for the conversion of starch."

The views of Dr. Hutchison are well expressed and distinguished throughout by sound, common sense, but they are, in the main, those of the majority of pediatrists. His opinions, however, with regard to the efficacy of gray powder administered to certain children who are unable even to digest peptonized milk, are somewhat novel and worthy of notice. He declares that he has treated children who were not able to assimilate food of any description, but who, when given gray powder, quickly improved and absolutely seemed to fatten on it, nor were these children necessarily the victims of congenital syphilis.

## News of the Week.

**Vital Statistics of Philadelphia.**—For the week ended October 24 there were reported to the Philadelphia Bureau of Health 390 deaths from all causes, as compared with 387 for the previous week, and 416 for the corresponding week of the preceding year. There were reported also 80 cases of typhoid fever, with 5 deaths; 59 cases of scarlet fever, with 2 deaths; 56 cases of diphtheria, with 9 deaths; and 9 cases of smallpox, with 8 deaths.

**The Enno Sander Prize.**—Two prizes will be awarded at the meeting of the Association of Military Surgeons of the United States for the best essay on "The Relation of the Medical Department to the Health of Armies." The first prize is a gold medal of the value of one hundred dollars; the second, a life membership in the association, of the value of fifty dollars. Competition is open to all persons eligible to Active or Associate Membership in the Association of Military Surgeons of the United States. The prize will be awarded upon the recommendation of a board of award selected by the Executive Committee. In fixing the precedence of the essays submitted, the Board will take into consideration—primarily—originality, comprehensiveness, and the practicability and utility of the opinions advanced; and — secondarily — literary character. Essays should be between ten thousand and twelve thousand words in length, exclusive of tables. Each competitor should send three typewritten copies of his essay in a sealed envelope to the secretary of the association, so as to reach that officer at least one month before the next ensuing annual meeting, in the present case on or before September 10, 1904. The essay must contain nothing to indicate the identity of the author. Each one, however, will be authenticated by a nom de plume, a copy of which shall at the same time as the essay, be transmitted to the secretary in a sealed envelope, together with the author's name, rank, and address. The award will be made at the next succeeding annual meeting of the association. The successful essay becomes the property of the Association of Military Surgeons of the United States, and will appear in its publications. The Board of Award for 1904 consists of Lieutenant-Colonel John Shaw Billings, U. S. Army; Brevet Brigadier-General George Ryerson Fowler, New York; Surgeon Henry Gustav Beyer, U. S. Navy.

**Erie Railroad Surgeon's Association.**—A meeting of this society was held at Hotel Rider, Cambridge Springs, Pa., October 13 and 14, under the presidency of Dr. C. L. Stiles of Owego, N. Y. The following officers were elected for the ensuing year: *President*, Dr. S. B. Hiner of Lima, Ohio; *Vice-President*, Dr. F. A. Goodwin of Susquehanna, Pa.; *Secretary* and *Treasurer*, Dr. J. A. Allis of Montclair, N. J. Drs. J. MacDonald, Jr., and E. Franklin Smith of New York were elected honorary members. The next place of meeting will be Chicago, Ill.

**For the Prevention of Tetanus.**—At the Twenty-ninth annual session of the Mississippi Valley Medical Association held at Memphis, October 7-9, resolutions were adopted deploring the fact that

more than 400 deaths from tetanus occurred following the 4th of July celebration of 1903, as shown by the statistical report elaborated by Dr. S. C. Stanton of Chicago. The great majority of these, it was believed, might have been prevented had proper precautions been taken. The conclusions which follow, as offered by Dr. Stanton in a paper presented before the association, were endorsed as the sense of the association: (1) Enforcement of existing laws regarding the sale of toy pistols and other dangerous toys. (2) Enactment of laws by the Nation, States and municipalities prohibiting the manufacture and sale of toy pistols, blank cartridges, dynamite canes, and caps, cannon crackers, etc. (3) Open treatment of all wounds, however insignificant, in which from the nature or environment there is any risk of tetanus. (4) Immediate use of tetanus antitoxin in all cases of Fourth-of July wounds, or wounds received in barnyards, gardens, or other places where tetanus infection is likely to occur. (5) As a forlorn hope, the jection of tetanus antitoxin after tetanus symptoms have appeared."

**The National Association for the Study of Epilepsy** will hold its third annual meeting in the Hall of the College of Physicians in Philadelphia on the afternoon and evening of November 5 next, under the presidency of Dr. Wharton Sinkler. The program includes the titles of a number of interesting papers. The association extends a cordial invitation to all persons interested in charity, and especially in the care and treatment of epileptics, to attend its annual meetings. Applications for membership may be made to the president or to Dr. Wm. P. Spratling, Sonyea, N. Y., secretary.

**Hospital for Consumptive Children.**—At the recent annual meeting of the New York Association for Improving the Condition of the Poor, John Seely Ward, Jr., presented an informal report upon an investigation he had made regarding hospital for tuberculous children, public baths, and forms of popular amusement in England and on the continent. At the close of the report he recommended that the association undertake the construction and maintenance of a hospital in or near New York to be especially devoted to the treatment of poor children suffering from tuberculosis. His recommendation was received with approval and was referred to the department of fresh-air work, with instructions to report to the trustees at the November meeting.

**Bureau of Vital Statistics Needed in Mississippi.**—Dr. H. A. Gant, President of the Mississippi State Board of Health, will, it is announced, present an appeal to the Legislature at its next session to establish a State bureau of vital statistics. He may also renew a former recommendation for the establishment of a State bacteriological laboratory.

**Smoking Forbidden at Syracuse University.**—A report from Syracuse announces that the Dean of the Medical Faculty of Syracuse University has posted a notice forbidding the smoking of cigars, pipes, or cigarettes in the college buildings. The Chancellor of the University was recently quoted as sanctioning the use only of fifty-cent cigars by the students.

**Dr. Frank W. Robertson,** superintendent of Elmira Reformatory, has resigned his position to take effect December 1. Joseph T. Scott, general superintendent of the Massachusetts State Reformatory, has been appointed to succeed him. Dr. Robertson went to Elmira about eight years ago as resident physician under Supt. Z. R. Brockway. He served about three years, and was made general superintendent to succeed Superintendent Brockway when the latter was removed.

**Spread of Smallpox in Philadelphia.**—Despite the active efforts of the health authorities smallpox continues to increase in Philadelphia, the number of new cases for the week ending October 17 being 54, as compared with 11 during the week before.

**Bequests to Boston Medical Institutions.**—Two medical institutions are the public beneficiaries under the will of Dr. George Haven of Boston, which was filed for probate on Monday of this week. The Harvard Medical School receives $25,000 outright and a share in a residue, and the Boston Lying-In Hospital received the doctor's books and instruments, a gift of $20,000, and shares equally with the Harvard Medical School in a residue.

**Philadelphia County Medical Society.**—At a stated meeting, held October 14, Dr. E. S. Bullock of Silver City, New Mexico, read a paper entitled "Six Years' Experience with Tuberculosis in the West." He pointed out that climate is by no means the most important therapeutic factor and that much could be accomplished in other ways, as by a life in the open air, a generous diet, and a proper adjustment between rest and exercise. Drs. Lawrence F. Flick S. Solis-Cohen, J. Madison Taylor, and Judson Daland took part in the discussion.

**Pathological Society of Philadelphia.**—At a stated meeting, held October 22, Dr. R. F. Stahl reported a case of hemorrhagic pancreatitis. The patient was a man, forty-two years old, who exhibited jaundice, with enlargement of the liver and finally fatal hemorrhage from the bowel. On post-mortem examination a large collection of partly organized and laminated blood-clot was found in the situation of the head of the pancreas. The gall-bladder was greatly distended and the liver was enlarged and its biliary passages filled with fluid. Dr. R. M. Randolph reported a case of probable coccidia of the kidney. The patient had had typhoid fever, in the course of which intestinal perforation had occurred. Operation was undertaken and two perforations sutured, but a fatal issue resulted. On making routine examination of the structure of the kidney, bodies were found that corresponded in their characters most closely with coccidia. Drs. J. H. Musser and J. D. Steele reported a case of amœbic abscess of the liver. The patient had suffered from dysentery, and a tumefaction appeared in the region of the liver. The abdomen was opened and fluid removed from an adventitious cavity. On examination the fluid was found sterile, and to contain a small number of leucocytes and red blood corpuscles, a certain amount of detritus and a number of bodies that for want of other identification were thought to be amœbæ. The fresh stools had been examined and no amœbæ were found in them. Dr. Joseph McFarland reported a case of pseudo-parasitism caused by the meal-worm. The specimens exhibited were obtained from the urine of a child who had presented no symptoms of illness, and it was suspected that the worms were passed by the bowel, having obtained entrance into the intestinal canal with farinaceous food, which the child was accustomed to take. Dr. McFarland exhibited also a parasite hitherto undescribed, that he had found accidentally in the body of a mouse inoculated with pneumococci. The organism appeared to be a sporozoon, but there had been no opportunity for further study. Dr. W. W. Hawke exhibited a specimen of hemorrhagic pachymeningitis from a case of paretic dementia in which the effusion of blood had taken place on both sides of the brain. The newly formed membrane was perfectly color-

less and entirely detached from the overlying dura. Dr. A. O. J. Kelly exhibited a specimen of indurative mediastinopericarditis obtained from the body of a girl whose principal symptom was anasarca, beginning in the lower extremities. The pericardium was greatly thickened and in places of almost cartilaginous density. The condition corresponded with one form of what has been designated multiple serositis. Dr. C. Y. White exhibited a specimen of abscess of the wall of the left ventricle and perforation of a mitral leaflet. The case has been one of general pyæmia following an abscess of the foot.

**Death at a Football Game.**—Robert E. Lewin of Plainfield, N. J., right guard of the Baltimore Medical College football team, dropped dead on October 21, at Annapolis, while engaged in the match against the Naval Academy eleven. He was seized with an attack of cardiac syncope just before the close of the first half, and died shortly after being carried from the field.

**A Chair of Orthopedic Surgery at Omaha.**—It is announced that Mr. J. Ogden Armour will found a professorship of orthopedic surgery at the Omaha Medical College, the endowment being sufficient to provide a salary of $5,000 for the incumbent of the chair.

**A New Harlem Hospital.**—Ground was broken last week for the new Harlem Hospital on Lenox Avenue, between One hundred and thirty-sixth and One hundred and thirty-seventh streets. Dr. John W. Brannan, president of Bellevue and Allied Hospitals, was present, but there were no formal exercises. The hospital will be eighteen months in building and will cost upward of $400,000.

**Bethlehem Free from Cholera.**—The outbreak of cholera reported last week at Bethlehem was of very brief duration, announcement being now made that it has been stamped out and that the cordon of troops has been removed.

**Plays for the Orange Ambulances.**—Arrangements are being completed for the annual series of dramatic performances this coming winter in Orange Music Hall, Orange, N. J., for the benefit of the Orange "Record" Ambulance Fund. These performances have been given for many years, the ambulance service for all the Oranges being entirely maintained thereby. Four subscription performances are usually given.

**An Attack on Basket Ball.**—At a recent meeting of the New England Association of Colleges and Preparatory Schools, Miss Lucille Eaton, a member of the Boston Physical Education Society, read a paper denouncing the game of basket ball as played by college women and school girls. Basket ball, she said, should be absolutely forbidden so far as girls under the college age is concerned, and it should be admitted only tentatively, and under medical supervision to a place among the sports open to women of more mature age. Among the objections which she urged against the game were the physical effects upon young girls at the beginning of menstrual life, the chances of permanent injury to beauty and health, the evil influence of such excitement upon the emotional and nervous feminine nature, and the tendency to unsex the player, for she declared that the competitive game with its traveling about, its exhibitions before mixed audiences, and its cultivation of the will to win at any cost spirit was not womanly and made [illegible]

**Award of the Nobel Prizes.** [illegible]

**Lectures on Tuberculosis at the Phipps Institute.**—The first of the series of lectures on tuberculosis to be delivered during the coming winter under the auspices of the Phipps Institute in Philadelphia was delivered on October 24 by Dr. E. L. Trudeau. His subject was "History of the Tuberculosis Work at Saranac Lake." A reception was tendered Dr. Trudeau at the close of the address.

**Obituary Notes.**—Dr. MAURICE FIESCHOR PILGRIM of this city died on October 18 of pneumonia. He was born in New Jersey. He obtained his medical degree in 1884 and for two years engaged in medical practice in this city. He then went to Europe and took up the study of diseases of the nose, throat, and ear, and at the end of a year returned to this country and began the practice of his specialty in Boston. He later became an earnest advocate of mechanical therapeutics and electrotherapy. He was a member and ex-vice-president of the American Electrotherapeutic Association, and at the time of his death was chairman of the executive council of that society.

Dr. JOHN L. WALDIE of this city died at his home in Brooklyn on October 18, after an illness of two weeks, at the age of thirty-two years. He was born in Brooklyn and was graduated from the Long Island College Hospital in the class of 1895. He was assistant attending neurologist to St. Mark's Hospital and was a member of the Kings County Medical Society.

Dr. LUDWIG SPANG FILBERT died in Philadelphia on October 19 at the age of seventy-eight years. He was a graduate of the medical department of the University of Pennsylvania in 1847. He was Quarantine Physician at the Port of Philadelphia from 1857 to 1860. Later he invented a patent pavement, and his subsequent career was devoted to mercantile pursuits.

Dr. JOHN K. LINEAWEAVER died at Columbia, Pa., on October 18. He was a graduate of the Jefferson Medical College in the class of 1861, and for twelve years was president of the Columbia Board of Health.

---

**Medical Gymnastics and Massage in the Treatment of Sprains.**—Carl Kellberg states that Beighman treated 145 cases of sprain with massage and gymnastics. All were completely restored. Thirty-five out of thirty-eight additional patients who came from nine days to three months after receiving the injury, were also cured. Treatment should commence as soon after injury as possible, or as soon as the swelling has ceased to increase, and should continue until complete restitution is accomplished, preferably two treatments a day, each of about twenty minutes' duration. Usually the tenderness is at first too great to allow any manipulation of the swelling itself, in which case the treatment may begin with effleurage or strokings above and below the inflammatory area in the direction of the vein and lymph stream. As tenderness diminishes the strokings may increase in strength. When resorption is fully established and the tension of the tissues becomes less, friction is added consisting of circular manipulations, either with the thumb or the tips of the fingers, at first lightly but later with considerable pressure. Special attention should then be paid to the grooves and depressions between the bones and other places which have not been accessible to effleurage. Exercises are now added, beginning with light passive movements in all directions in which the joint is capable of moving. As the power of the joint improves active movements are added, at first with, later without, the resistance of the operator. If pain is returned or if there be hemorrhage into the joint the movements should be postponed.—*The Chicago*

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

REVERENCE AND HOPEFULNESS IN MEDICINE—LONDON'S DEBT TO MEDICINE—AMERICA TO BE APPEALED TO BY A BONE-SETTER—CANCER—SATURDAY AND SUNDAY FUNDS—THE KING'S SANATORIUM—THE LATE MR. WALSHAM.

LONDON, October 9, 1903.

THE London schools are now at work and the provincial Scots and Irish will follow a little later. Some of them began on the traditional 1st. The new University of Liverpool on that day opened its first public work. The Faculty of Medicine it was that was thus first in the field and the inaugural address was delivered by Sir Dyce Duckworth. As a Liverpudleian, born and partly educated in the city, he confessed that his retrospect was amazing and his wildest anticipations never projected such a future as the medical school has attained in this new university. Then he mentioned some of the names who are not to be forgotten in connection with the movement for establishing the university, and traced the development of the city and this seat of learning. Among the names recalled were: Drs. Currie, Dobson, Shepherd, Trall, Yates, Brandreth, Boston, and other lights of literature, science, and medicine who were natives of Liverpool, including W. E. Gladstone and Bishops Carpenter and Lightfoot, as well as Dean Stanley. In more recent times a number of workers were also mentioned, and now that the university is founded on a firm basis Sir Dyce insisted that the passport to a degree in any faculty should be the completion of the full curriculum in arts. He also urged that the hospital schools should henceforth be devoted entirely to the study of disease and its treatment and that none of the energy of these should be expended on teaching ancillary subjects. This plan has been wisely adopted here, and he looked for the same provision elsewhere in the near future.

From this point Sir Dyce Duckworth proceeded to discourse on "Reverence and Hopefulness in Medicine." He remarked that the habit of reverence was always becoming, but he feared it was not so commonly met with as formerly. The spread of democracy need not entail bad manners. But of late he has observed a laxity of manners and conduct compared with former years. Such conduct, if not immoral, was certainly a sign of bad breeding.

In the second part of his lecture he said hopefulness in medicine was in these days prominent—little or nothing appeared to darken it. If they were not now inspired by hope they never would be. It is a gift to be cherished now and always. He had to admit that there had always been optimists and pessimists among practitioners. It was very damaging to make a fatal prognosis and for it to be proved false. It is as bad to raise false hopes which are not fulfilled. Yet there is a measure of hopefulness to be carried to the bedside and it helped remedial agents. A rational degree of hopefulness will become the physician. Sir Dyce concluded with the solemn and beautiful words of advice of the late Sir Thomas Watson to remember, "in your most successful efforts you are but the honored instruments of a superior power."

University College delayed opening the session of her Faculty of Medicine until the 5th inst., when Prof. Sidney Martin, as Dean, read his report. It stated that during the past year the arrangements for the incorporation of the College in the University of London had been adopted, and progress made toward the execution of the scheme, but funds were required for further buildings.

Prof. E. H. Starling then delivered an introductory lecture and took for his subject "London's Debt to Medicine." He referred to the many benefits to mankind conferred by medicine and asked what part London—both the profession and the community at large—took in the recognition of the work. He said the system in the hospital schools disclosed an absence of academical ideals—a void which, he held, could only be filled by establishing a great central medical school similar to the State-aided schools of Germany, the general working of which he went on to describe. The initiatory steps for founding such a school ought to be undertaken by the university, and it should have one object, the advancement of medicine, and so not detract from the present medical schools. It would cost money, but that would be supplied by philanthropists without appealing for government or municipal assistance. The great thing at present was to recognize the need of such a new departure, which he earnestly advocated.

American surgeons, look to your laurels! Mr. John Atkinson, F.R.C.V.S., having demolished Lorenz and found that "the medical body of England condemns hundreds of children annually to a life of wretchedness for the sake of a mere point of etiquette," announces in the newspapers that he is coming to the United States to render his help in special cases. He says he succeeded to the practice of the Huttons—so I suppose we may take him as the leading "bone-setter." As a further introduction he remarks "it is no boast to say that as a Fellow of the Royal College of Veterinary Surgeons, and as a medallist in comparative anatomy, I hold as high a certificate of capacity as can be awarded in this country." Nevertheless, he finds in spite of this wonderful certificate that the medical men of this country decline to recognize him as qualified to practise on children, or let him "work under their own supervision for the relief of cases which they openly confess their own inability to cure." So he is coming to you and will "invite the press to select" cases which have been "pronounced intractable" for him to treat at his "own residence" by his "own methods," and when his treatment is completed he will submit the "patients to the investigation of the profession." This great offer is made "in the interests of suffering humanity alone," so beware of rejecting it lest you come into the same condemnation as the effete old country whose surgeons decline to surpervise the practice on crippled children of the bone-setter who is a Fellow of the College of Veterinary Surgeons. I don't know that the other Fellows of that respectable college are particularly proud of the successor to the Huttons.

The newspapers are circulating a statement that Professor Fabiani of the Palasciano Institute, Naples, has discovered a serum for the cure of cancer, and that he has found organisms in the disease differing from any previously described. He is shortly to make scientific communications on the matter.

The Hospital Saturday Fund's collection so far for this year is not discouraging. Up to the end of September the general collections reached £10,197, as against £9,995 for the same period of last year, but the accounts were kept open a week longer in 1902.

The collection of the Sunday Fund is the best this year that it has ever had, over £63,000.

It is announced that the King will himself lay the foundation stone of his Sanatorium for Tuberculosis.

St. Bartholomew's has lost one of the senior surgical staff in Mr. W. J. Walsham, who died on Monday, in his fifty-seventh year. He was a Bart's student, went to Aberdeen and graduated there in 1871. Afterward took the F.R.C.S. (1875), and has had a distinguished career both as surgeon and teacher. He has also been examiner at the college and at Apothecaries' Hall. You will remember his text-book of "Surgical Pathology" and perhaps better still his "Surgery, Its Theory and Practice," which reached a seventh edition. He was an active member of the societies and contributor of various papers. He wrote the articles on the nose and on orthopædic surgery for Treves's work; the pharynx, vasopharynx, and ulcers in Heath's Dictionary of Surgery, and many papers in the St. Bartholomew's Hospital Reports, the Medico-Chirurgical Transactions and the weekly journals. Perhaps his favorite subjects were deformities and nasal diseases.

---

## OUR BERLIN LETTER.

(From Our Special Correspondent.)

PROFESSOR BEHRING ON TUBERCULOSIS—PROPHYLAXIS OF TUBERCULOSIS—OPERATIONS FOR INTUSSUSCEPTION—DISEASES WHICH FORBID MARRIAGE—INCREASE OF HEART DISEASE IN THE GERMAN ARMY—PLACES BOYCOTTED BY THE PROFESSION—OBITUARY.

BERLIN, October 2, 1903.

BERLIN medical life has been transplanted recently to two places: to Kassel in Hessen-Nassau, where the Congress of German Physicians and Naturalists was held, and to Brussels in Belgium, where the Ninth International Congress of Hygiene took place. The first was of more especial medical interest. Among the well-known scientists present were Behring, Ladenburg, Naunyn, van't Hoff, Allan Macfadyn, and Ramsay. The question of bovine and human tuberculosis was discussed at both places. At Brussels, Kossel of Berlin, Arloing of Lyons, de Jong of Leyden, and Gratia of Cureghem discussed the question whether human tuberculosis and tuberculosis of domestic animals are due to the action of the same tubercle bacilli. On this question the Congress voted the following resolution: Human tuberculosis generally originates from man, but, as has been proved by modern experiments, it is necessary to observe all precautions to prevent the possibility of an infection through animals.

Professor Behring at Kassel answered the question in the same terms. According to the experiments made

at Marburg, human and bovine tuberculosis have the same origin, and it would be detrimental to the public health to neglect precautions as to the cow's milk. Behring expressed the view that infected milk is the principal cause of tuberculosis in infants. The adult is able to protect himself from the noxious influence of the Bacillus tuberculosis by means of the alexins of his body conferring upon him practical immunity. But as infants do not possess alexins they are naturally more prone to become infected. Behring said he was working on a protective serum with which to inoculate young children. But as his experiments have not yet been concluded he did not wish to give details of the composition of this serum.

Tuberculosis and pregnancy was the subject of Dr Veit's paper. Experiments have proved that the tubercle bacillus penetrates the placenta and may infect the child, and that the state of the pregnant woman may become worse through her own tuberculous infection. For this reason Hegar holds that in all cases of tuberculosis of pregnant women abortion should be induced. This is, according to Veit, an exaggerated demand, as very often pregnant women gain in weight more than the normal weight of the child, and they bear a healthy child without harm to themselves. The indication for abortion is furnished by changes in the weight of the woman. If no increase results then abortion is necessary. But under no circumstances ought abortion be procured if the woman is increasing in weight.

Dr. Braun read a paper on intussusception. This condition is rare in Germany, less frequent than in England for instance. The cause is a spasm of the intussusceptum, not a paralysis of the intussuscipiens. Acute cases are easily diagnosed in children when tenesmus, vomiting, and bloody diarrhœa occur with collapse. Operation gives the best results; high injections of air or water may prove beneficial, but if the patient does not recover within forty-eight hours there should be no delay in operating. The establishment of an artificial anus only means protracted death, and children in whom resection is made generally die too, therefore disinvagination ought to be done as soon as possible. Resection is preferable for adults. Dr. Kredel supported Dr. Braun's view that resection was the best operation for adults, for from disinvagination he did not anticipate any good results.

Some interesting remarks on the diseases which contraindicate marriage were made by Dr. Fellner. Tuberculosis of the lungs in advanced stages, phthisis laryngis, mitral stenosis, myocarditis, chronic nephritis, and cancer contraindicate marriage. In a second group, comprising chorea and severe epilepsy, it must be left to the physician's own judgment whether marriage ought to be allowed or not. Dr. Rehn discussed the value of the leucocyte count in appendicitis. He thought the method was of no value, although a large abscess may be diagnosed without it. According to his statistics, furthermore, there were cases in which there had been no increase of the leucocytes, although the operation showed the presence of a small collection of pus.

The report of the commission on the causes of the increase of heart disease in the German army has just been published. Dr. Stricker says that the causes are overwork of growing boys, no rational leisure between the hours of work, too early use of alcoholic drinks and of tobacco, too much cycling and rowing. Combined with these are often hysteria and neurasthenia. Rheumatism, and especially influenza, most frequently cause heart disease. Medical men in Germany are waking up to the importance of several social questions in the profession. The club system (Kassenvereine) has reduced the income of many doctors to a minimum, demanding hard work and little pay. Great opposition has been made to these clubs and societies, and recently resort has been had to a trial of the boycott. An organization, at the head of which is the Medical Union of Leipzig, is boycotting places all over Germany, where the directors of the clubs, mostly members of the working-classes, have tried to impose on the doctors unfair payments. One of the places boycotted was Mühlhausen in Thüringia, and *mirabile dictu* the whole German profession has stood together, no doctor came to Mühlhausen and the Mühlhausen clubs had to give way and pay all expenses. Stettin and Braunschweig, places of 100,000 inhabitants, are boycotted to-day, and in every medical paper we read announcements: "Cave Stettin, Cave Braunschweig." The number of the boycotted places amounts to nearly a dozen to-day. The Government is taking a hand in the matter, and a new law is to be brought before the Reichstag dealing with the quacks, a numerous body in Germany. The fact though remains that the number of physicians is too great at present in relation to the population. The number of physicians may gradually decrease in the next decennium, as the number of medical students at the universities is becoming less from year to year.

## THE PLAGUE IN PERU AND CHILI.

(From Our Special Correspondent.)

AREQUIPA, PERU, September 19, 1903.

SINCE my last letter I have received the Bulletin of the National Academy of Lima for August. This sets forth clearly the clinical history of the first-recognized cases of plague in Callao. The 28th of April seems to have been the date of the first. Now it is reported as existing in Pacasmayo, Mollendo, and Iquique.

What strikes one—so far as one can learn—is that it does not seem to be very contagious, and that it is not so fatal as in other parts, the cases being comparatively few as yet and many responding satisfactorily to serum injections. Gradually people are beginning to see that an effective quarantine is impossible, so hygienic measures are taking more prominence.

Let us hope that these measures, assisted by the brilliant sun which is said to destroy the germs in three hours, may prove effectual in stopping the spread of the disease.

Smallpox has again appeared in this town.

## VOMITING, GREEN STOMACH CONTENTS, APPETITE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I feel sure that Dr. Mark I. Knapp, who contributes an article on "Some of the Mistakes We Have Inherited," to your issue of September 19, will not be offended at my confessing to be one of the heirs.

Dr. Knapp holds that vomiting is never reflex, but always due to a spasm of the stomach or intestine and, in turn, due to irritating material. Even the action of irritating contents seems to me to be a reflex one, but, as a matter of common observation, extrinsic reflex vomiting does occur. Why is it that ordinary gastric contents or a few drops of mucus become highly irritant to the mucous membrane when one passes from dry land to a boat? How does a hair in the butter on the plate suddenly transform agreeable food into irritating gastric contents? How about the man who tied his room mate in order to commit suicide without interruption, swallowed poison and was saved by the filthy stories which his chum narrated? This may be a myth, but it certainly is based on a well-known psychic reflex.

Green vomit may be invariably due to green mold in New York, but in Buffalo it is usually due to bile, and stomach contents set aside, under a cotton plug, develop white or black mold more frequently than green. Dr. Knapp has very kindly verified for me one of the few cases of green stomach contents that I have encountered, in which the color was due to mold. Dr. Knapp further states that, while bile may be present, it is yellow instead of green. Quite a few years ago, I called attention to the fact that the yellow or green color of stomach contents was fairly reliable evidence of the absence or presence, respectively, of free hydrochloric acid, which acts as an oxidizing agent. Some time ago, I was surprised to withdraw stomach contents tinged with yellow and showing considerable free HCl on immediate titration. But, within a few minutes, the characteristic green color spontaneously developed, and I then recollected that the yellow tinge had occurred only in the last portion of chyme aspirated, the bile evidently having entered the stomach during the process of extraction.

The relation of appetite to the state of contraction of the stomach is not easily demonstrated by experiment, yet it seems to me that the old view that appetite depends upon an inequality between cellular demands and nutritive supply is more rational than the theory that it depends upon a purely gastric condition. For instance, persons with large gastric areas may be hungry and those with small areas may have a distaste for food. After the tremendous muscular exertion to squeeze a few drops of liquid from the stomach during seasickness, it is reasonable to suppose that the patient's stomach is contracted—in addition to the evidence afforded by ordinary or auscultatory percussion—yet the appetite does not usually return. I agree practically with Dr. Knapp's view that the appetite disappears when the stomach relaxes, but would express it rather differently: Satiety is due to the stretching of the rugæ, not to a true relaxation, and hence, persons with dilated stomachs often manifest boulimia—not necessarily as the result of genuine appetite or hunger—because a normal amount of food does not cause tension on the rugæ.

A. L. BENEDICT, M.D.

156 W. CHIPPEWA ST., BUFFALO.

## A DOCTOR'S BUILDING.

To the Editor of the Medical Record:

Sir: At various times we have heard of plans for a building devoted exclusively to doctor's offices, similar to buildings of the same sort in other cities, but nothing has been said about the plan of late. It is practically certain that such a building would give a good return for the investment, as there are hundreds of physicians, specialists chiefly, who would be glad to avail themselves of offices away from their homes. This would be particularly true of a building situated centrally, and near to the Academy of Medicine, and the Public Library, where library facilities would be closely at hand. In such a building consultants would be grouped together in such a way that one could readily avail himself of special information desired in any given case and various laboratories could be carried on to the advantage of those of us who are so busy as to be a little neglectful about giving our patients the best and latest resources. Offices could be so fitted up that we could have special office facilities with dark rooms, compressed air, *x*-ray apparatus, and numerous conveniences that are desirable and expensive when wanted for a private house, but less expensive when managed for a large number of physicians in some public building.

The argument that undesirable tenants would be the first to choose such quarters can be answered as it has been in other cities. For that matter, it would be easy to limit tenants, and admit only those who are members of the responsible medical societies.

Medicus.

# Progress of Medical Science.

*Boston Medical and Surgical Journal, October 22, 1903.*

**A Hitherto Undescribed Membrane of the Eye and Its Significance.**—Frederick Herman Verhoeff concludes: In the pigment layer of the retina there is a fenestrated membrane identical in structure and staining reactions with the membrana limitans externa. The rods and cones are not nervous elements, but modified ependymal cells, and are analogous to sensory epithelium. The limiting membrane of the rosettes of glioma retinæ is a fenestrated membrane similar in every way to the membrana limitans externa, and the rosettes correspond to the neuro-epithelium of the normal retinæ. The stricture of the limiting membrane of rosettes explains why they assume their characteristic spherical and spiral-like forms. "Neuro-epithelioma retinæ" is no more suitable than "glioma retinæ" for the class of tumors to which these terms have been applied.

**Lesions that Augment the Development of Tetanus and Other Infections in Gunshot Wounds.**—Louis A. La Garde states that lesions will appear in the parts beyond the channel made by the projectile, to an extent dependent upon: (1) The sectional area of the bullet. (2) Its velocity. (3) The resistance encountered on impact. The greater the velocity or sectional area of the bullet the greater will be the lesion in the surrounding tissues. In those cases in which the velocity is great, and the resistance on impact unyielding, the destruction is enormous. Slough often occurs in the skin beyond the margins of entrance and exit. When healing is well along, a cord marking the track of the bullet in the soft parts is easily discernible to the sense of touch. Hæmatomata especially predispose to the development of infections. Burn adds to the susceptibility. The extent of the hæmatoma increases with the velocity of the orojectile to a marked degree. Destructive effects increase with the sectional area of the bullet. The thoroughness with which tissues are often infected by the energy of an unclean bullet has a great bearing upon the susceptibility to infection. Among the lesions of gunshot wounds which predispose to infection, another important factor is the fissuring, extending laterally from the channel track, and the disturbance of the muscle or tissue fibers, which is apt, ultimately, to lead to necrosis of the same.

**The Condition of the Vasomotor Neurons in Shock.**—W. T. Porter declares that in shock the primary injury lies outside nerve cells. The symptoms which characterize shock have often been ascribed to a depression of the vasoconstrictor nervous system. Each of the nerve chains which constitute the vasoconstrictor nervous system has three neurons. The cell body of the first lies in the bulb; its axis cylinder process ends in the spinal cord, or in the bulb itself, in physiological contact with the second neuron. The cell body of the second neuron lies in the cord or bulb, but its axis cylinder process leaves the cord and ends in physiological contact with a sympathetic cell. The sympathetic cell is the third neuron. Its axis cylinder process ends in the wall of a blood vessel. The bulbar cells or first neurons affect the blood vessels only through the second and third neurons. Consequently, if stimuli which pass through apparent nerves to the bulbar cells call forth a normal change in the caliber of the blood vessels, the condition of all three neurons must be normal. The depressor nerve connects with all the bulbar vasoconstrictor cells alike. The fall in blood pressure caused by the stimulation of the central end of the depressor nerve is, therefore, a quantitative test of the condition of all the vasoconstrictor neurons, those of the first order, in the bulb, and those of the second and third order, through which alone the bulbar neurons can alter the constriction of the blood vessels. If, therefore, the stimulation of the central and of the depressor nerve produces as great a fall in blood pressure during shock as before shock began, the condition of the three vasoconstrictor neurons must be normal even in shock. Exhaustion in the vasoconstrictor neurons therefore cannot be the essential cause of the symptoms ermed "shock."

*Journal of the American Medical Association, Oct. 24, 1903.*

**Sarcomatous Transformation of Myomata.**—T. S. Cullen states that myomata showing sarcomatous degeneration are developed from two sources: (1) Connective tissue, leading to spindle or round-celled formation, and (2) uterine muscle. Clinically, it is noted that a myomatous uterus, after being dormant for possibly several years, becomes the seat of a rapid enlargement. If the growth is submucous, portions may be expelled from time to time, and there is an offensive discharge with cachexia. From recent laboratory investigations the following rules for operative intervention may be laid down: (1) Whenever sarcoma or carcinoma may coexist with myoma panhysterectomy is imperative—not amputation through the cervix. (2) Bisection of the uterus is contraindicated where there is a possibility of a malignant growth developing in or associated with the myomatous uterus (3) In every case of hysteromyomectomy it will be advisable to have an assistant open the uterus immediately on its removal to determine if carcinoma of the body exists and to find out whether the myoma has become sarcomatous. If malignancy is detected the cervix can thus be removed without delay.

**A Case of Aerogenes Capsulatus Infection of the Neck.**—The patient of L. Leroy was a colored man aged twenty-three years, with the history of a "sore throat," and considerable cervical swelling in the region of the left tonsil. The progress of the case led to a diagnosis of suppurative cellulitis. Incision gave exit to a little dark colored fluid, but no pus. After the second day the skin below the incision slowly separated from the subcutaneous tissue, until at the fourth day a gangrenous area was present, reaching from the ear to the clavicle, and discharging a light sanguineous fluid from an opening at the lower edge. About the fifth day the skin was entirely separated, leaving the muscles beneath clearly exposed. The fibrous tissue rapidly became destroyed, leaving the underlying muscles, vesicles, and nerves clearly exposed to view, as in the most careful dissection. The swelling was not extreme, and until the last day no emphysema or crepitation was present, and then only in small amount. Death occurred on the eighth day. Examination of discharge made six days before death, many bacteria were observed, but no streptococci. A few large bacilli were found, judged to be Bacillus aerogenes capsulatus, though the author was unable to demonstrate any capsule, and based his diagnosis on culture reactions.

*Medical News, October 24, 1903.*

**Congenital Hypertrophic Stenosis of the Pylorus.**—B. G. A. Moynihan declares that the symptoms of the disease are strikingly similar in the majority of the recorded cases. The child at birth is of normal weight and healthy. Soon it is noticed that it begins to vomit after its food. At the first it is only after the completion of a meal or toward the end that the food is returned. The quantity vomited increases day by day It is little altered from its condition when swallowed, only a little mucus is added. Bile is never present in the vomit. When the vomiting is thoroughly established as an enduring symptom its violence is remarkable. Weight is steadily lost. The temperature is constantly subnormal. Constipation is almost invariable. The abdomen is shrunken and hollow. The stomach is dilated or hypertrophied with visible waves of peristalsis. If with all these symptoms a transverse epigastric tumor be found, the diagnosis of pyloric stenosis can no longer be in doubt. No very satisfactory explanation of the causation of the condition has yet been given. Further investigation is necessary. Spasm at the pylorus and in the body of the stomach is a condition which can be seen from time to time on the operating table. Before the vomiting has become incessant much good may be done by careful washing of the stomach and feeding in small quantities through an india-rubber catheter. The operations of pylorodiosis, pyloroplasty, and gastroenter-

ostomy have each been performed on several occasions, and their relative merits have not as yet been definitely determined. The statistical results up to the end of 1902 were as follows: Pyloroplasty had been performed three times successfully; in a fourth case, the relief being imperfect, a gastroenterostomy was done later with good results. This patient was sixty-seven years old. Gastroenterostomy always anterior had been performed nine times; five patients recovered, four died. In one, death was due to obstruction caused by a Murphy button. Loreta's operation had been performed nine times with seven recoveries.

*New York Medical Journal, October* 24, 1903.

**Tubal Pregnancy.**—M. D. Rushmore reports twelve cases operated on in hospital. The first group of four all presented a free hemorrhage into the peritoneal sac, three times from tubal rupture, and once from the dilated fimbriated end. In three cases the operation was done soon after the rupture when the patients were in a condition of extreme anæmia and partial collapse. In one case several weeks intervened between rupture and operation. All four cases were saved. The second group of eight cases all presented unruptured tubes distended with blood. The symptoms in all were pain and hemorrhage, and in all elastic masses were felt alongside of the uterus. All of this group were saved. As to evidences of pregnancy it is stated that in no case was a fœtus found; in one there was a fetal sac, in ten evidences of decidual formation were shown by the microscope, while in two no evidences of pregnancy were noted.

**Cancer of the Prostate.**—From a careful review of literature (the references being given), R. H. Greene lays down a general description of prostatic cancer, considering its frequency, age of the patient, the question of glandular metastasis, symptoms, prognosis, and treatment. He adds the notes of a case coming under his own observation. His patient was a man of fifty-nine years, who had had gonorrhœa at the age of nineteen. His prostatic symptoms commenced with slight burning or micturition, and a burning feeling in the perineum. On one occasion catheterization was necessary after excess in drinking wine. At that time only very slight enlargement of the right lobe of the prostate could be made out. The usual sedative measures failed and operation was considered. It was thought that either an encapsulated abscess or stone in the prostate was the cause of the pain. The prostate was removed through an opening into the urethra, breaking into the walls of the latter from the inside with a blunt instrument and digging out the side lobes with the finger. The rectum was slightly wounded and a small fistula resulted but gradually closed up sufficiently to give no trouble. At the present time, some fifteen months after operation, the patient is doing well. He has had two attacks of epididymitis since the operation and has noted a loss of sexual power. The pathologist's report of the tissue removed was that the right lobe of the prostate was cancerous, but that it presented a low grade of malignancy.

*American Medicine, October* 24, 1903.

**Funic Pulsations: When to Ligate the Cord.**—Wm. Harman Good declares that the funic pulsations are fetal in origin. To demonstrate this, the writer placed a hemostat on the cord. The pulsations on the maternal side immediately ceased, while on the fetal side they persisted. The stump was still pulsating, thirty minutes after the cord was tied off. In a vigorous child the cord may be ligated immediately, but in less vigorous children the cord should not be ligated till the pulsations cease. The funic pulsations are of fetal origin, and the first firm contraction of the uterus is the indication for the ligation of the cord.

**Treatment of Abscess of the Liver.**—Thos. L. Rhoads declares that No. 2 abscesses are found in exactly the same location in the liver. Two methods as commonly used to locate the pus: Aspiration, and temporizing until the volume of pus has become so large that the evident swelling below the rib margin or toward the nipple, together with local signs of redness, œdema, bulging, or fluctuation, leave no doubt as to where the instrument must enter. Aspiration is unreliable, and danger is always associated with the process. The writer makes a direct palpation of the liver in every suspected case after a very careful examination of the case in all its aspects has satisfied the surgeon that pus exists. An exploratory incision is made 2 cm. below and parallel to the right costal border. A methodic digital examination of the liver is made. When the pus is located, there are but two routes for its evacuation: Through the original incision, and through the chest wall. The abscess is incised and the cavity cleansed. After-treatment must be judicious. Feeding is very important. Olive oil is given thrice daily on an empty stomach. Milk should not be given. Foods must be chosen with the object of giving the large bowel rest.

*The Lancet, October* 17, 1903.

**On the Etiology of Bubonic Plague.**—J. A. Thompson has made extensive observations of two epidemics of plague which have occurred at Sidney. His general experience shows that neither direct nor indirect communication with the sick has any share at all in the diffusion of the disease; place infection almost certainly does not operate to maintain it; the sole source of infection for man is from rats, and probably through certain classes of fleas infecting those animals.

**The Treatment of Sciatica.**—J. M. Clark extols the virtues of Weir Mitchell's plan of immobilization of the limb by the long splint. He has employed this device in twelve cases. Eleven were men, their average being forty-nine years. The average duration before coming under observation was nearly six months; the average duration of treatment was five and a half weeks. Ten cases were cured. One had a severe relapse some weeks later, but was cured by a second course of treatment. One was not relieved, but he was a restless patient and would not keep the splint on. The restraint is at first very irksome and a hypodermic of morphine is often required the first night or two. The splint must be carefully watched and readjustment may be necessary, especially if pain appears in the foot, behind the outer malleolus or in the ankle.

**The Quantitative and Qualitative Relations of Toxin and Antitoxin.**—The following conclusions are offered by E. F. Bashford: (1) The volume containing the lethal dose can be converted into one no longer lethal within the time limit by diminishing the total volume by a small but measurable fraction of the whole. (2) A measurable quantity of toxin solution can be borne without the production of any symptoms. (3) The poisonous action of the lethal dose may be abolished within the time limit by the addition of a very small quantity of antitoxin; the experiment gives evidence of a qualitative reduction in the toxicity itself, but no evidence of the occurrence of the quantitative reduction referred to in conclusion (1). (4) When the toxic power of a quantity of toxin has been reduced by antitoxin to such an extent that no symptoms appear, a measurable degree of toxic power is still potent qualitatively, but we are not entitled to state this in the quantitative terms of conclusion (2). (5) The lethal dose is separated from the non-lethal not by a hard-and-fast line but by a zone wherein are contained appreciable fractions of the lethal dose; the data here are quantitative. (6) In mixtures of toxin and antitoxin in such proportions that a lethal issue occurs and does not occur, the margin between the toxic powers of such mixture is not sharp but is a zone, and the actions standing at the upper and lower limits of this zone differ from each other by a measurable fraction of the total toxicity; the data here are purely qualitative. (7) It is not justifiable to assume *a priori* that one volume of antitoxin solution always fully accounts for one volume of toxin solution when mixed in varying multiples. It is preferable to speak of the retention of active toxicity or of active antitoxicity in characterizing such mixtures. The phrases "free toxin" and "free antitoxin" may not be in accordance with the facts and should be abandoned.

*British Medical Journal, October* 17, 1903.

**Cystic Tumors of the Mammæ: Their Removal by "Forcible Massage" without Incision.**—Herbert Snow makes this report. The breasts of patients suffering from cysts of the mammæ are full of milk—a decomposing and more or less altered product. This is quite apart from pregnancy. The women are single, or have not borne a child for many years. If this milk secretion is squeezed completely out, all the trouble vanishes at once. The work must be done under anæsthesia. No inflammatory mischief follows the rupture. The large cysts should be ruptured subcutaneously; then the viscid yellow or greenish-black matter is squeezed from the nipple till no more can be expressed. The large cyst usually ruptures without force, but continued pressure, exercised in various directions, is needed before the retained secretions can be completely evacuated.

**The Pathology and Treatment of Hallux Rigidus, Hallux Flexus, and Hallux Extensus.**—A. H. Tubby is convinced that there is one cause underlying all the conditions, namely, an osteoarthritic condition of the first metatarsophalangeal joint. The writer insists upon the enlargement and inflammation of the intersesamoid pad as an essential factor in the production of the rigidity. The only operative treatment he has found effectual is to remove the head of the first metatarsal bone, dissect out

the part of hypertrophied and inflamed tissue between the sesamoid bones, and, if the surface of these bones should be ulcerated, to dissect them out from the tendons in which they lie. In many cases of rigidity the movements become, under an anæsthetic, entirely free, showing that the apparent loss of movement in the joint is reflex. After a time osteophytic outgrowths, especially from the base of the first phalanx, render flexion or extension impossible. Operation is the same as that for bunion. In less painful cases attention to the size of the boots, giving ample room to the big toe, is effectual. The boot should be long enough and the sole stiff enough to prevent any pressure on the end of the big toe in walking. It is also desirable to take off pressure on the metatarsophalangeal joint in walking, by a bar placed obliquely across the sole of the boot and well behind the heads of the metatarsal bones, so that the weight of the tread is not borne at the heads of these bones, but behind them.

*Deutsche medicinische Wochenschrift, October* 1, 1903.

**Circumscribed Gangrene of the Dura, and Subdural Abscess in the Posterior Occipital Fossa Due to Chronic Suppuration of the Middle Ear.**—B. Heine's patient was twenty-six years of age and had suffered since childhood with a chronic suppuration of the middle ear. The patient applied for treatment with symptoms of an acute mastoid involvement, and an operation for the same was immediately undertaken and an extensive suppuration of the mastoid cells revealed. Following the operation the symptoms were but little improved, and eight days subsequently, at a second operation, additional portions of the temporal bone were removed. This was followed by a marked increase in the discharge of pus. At subsequent dressings small pieces of the dura were discharged and at times considerable quantities of cerebrospinal fluid. Death eventually took place from pulmonary tuberculosis, and at autopsy the above lesions were found.

**Pathogenesis of Gonorrhœal Epididymitis and the Treatment of the Same by Puncture.**—Gustav Baermann says that epididymitis which develops during the course of a gonorrhœa is due to a local invasion of the gonococcus, and that these organisms can be cultivated with regularity from the puncture fluid. In the majority of these cases of epididymitis there occurs very quickly an abscess formation which has not hitherto been diagnosed by clinical means. Such suppurations are either pseudo-abscesses due to stagnation of the circulation and followed by secondary breaking down of the walls of the vas epididymitis, or they are pure abscesses which arise in the surrounding connective tissue and occasioned by the invasion of gonococci through the lymph channels. In all cases which go to suppuration a smaller or larger hydrocele develops, which is due to the invasion of the tunica vaginalis by gonococci. All cases of epididymitis, which occur in conjunction with attacks of non-gonorrhœal urethritis are due to a local invasion of the microorganism, which gives rise to such a urethritis. All cases of epididymitis which set in with pronounced symptoms should be treated by early puncture, since by so doing the chances of subsequent abscess formation are materially lessened. In all cases the hydrocele should also be punctured in order that the pressure may be relieved and conditions favorable for absorption established.

*Berliner klinische Wochenschrift, October* 5, 1903

**Orthostatic Albuminuria.**—Otto Jacobson, under this classification, considers that form of albuminuria which is dependent for its existence upon a change in the position of the individual—from a vertical to a horizontal. The albumin is never present during a maintained vertical or horizontal position, but appears in the urine shortly after a change from one to the other. In the vast majority of instances, persons affected with this form of albuminuria are of an intensely nervous disposition, and give an hereditary history of neurasthenia or pathological nervous diseases. It is almost exclusively limited to the time of puberty, and is to be regarded as a form of the so-called "puberty" albuminuria. The amount of albumin present may vary from a mere trace to a considerable quantity, and hyaline casts may, at times, be present. For a diagnosis it is necessary for the albumin to vanish when the patient is placed and maintained in the horizontal position. Furthermore, the change from albuminuria to an albumin-free urine occurs under the proper conditions with marked celerity.

**Action of Heat and Light Rays upon the Temperature of the Skin.**—Ernst Sommer shows that the temperature of the skin covering joints affected with chronic diseases is lower than normal except during acute exacerbations when the reverse is the case. The application of heat and light rays causes an increase in the cutaneous temperature of the regions thus treated over that of the non-treated portions. Nevertheless, there are cases in which following the use of the rays the temperature of all portions of the skin is lower than previous to such application. The reduction in the temperature of the collateral side does not occur with the same regularity under the application of the rays as is the case when hot and cold applications of other nature are used. The immediate heating effect of the short is more lasting than that of the long waves. After two to four hours the temperature of the treated and untreated regions becomes reversed—that is, the former is cooler than the latter. This appears to be due to a reactive action in the portions of the skin which have not been submitted to the action of the rays.

*Münchener medicinische Wochenschrift, October* 6, 1903.

**Acute Inflammation of the Cæcum.**—Reisinger reports two rare cases of acute inflammation of the cæcum (typhlitis) in which the appendix was in no way involved. All authors agree that such a condition is extremely rare, and that such is the case is apparent from the fact that the two cases here recorded were the only instances of this kind which occurred among 350 which were operated upon under the symptomatology of acute appendicitis. The diagnosis between these acute inflammations and appendicitis is not possible, and the true condition can only be determined at the operation.

**Significance of the Increase of Erythrocytes in Congenital Heart Affections.**—E. Fromherz reports seven cases in detail, but comes to no definite conclusions regarding the pathogenesis of the increase of the red blood cells. One of the cases which was submitted to numerous blood counts would seem to uphold the theory of Arcangeli, who regards the increase as compensatory in nature—that is to say, the deficient oxydation of the blood is sought to be compensated by an increase in the production of erythrocytes by the blood-forming organs. In this case several attacks of cyanosis and dyspnœa occurred, and in every instance during such attacks the number of red blood cells was markedly reduced below the normal. Other of the cases go to show that in many instances the cyanosis observed in these cases is to be regarded as a "mixture-cyanosis"—that is, a mixture of arterial and venous blood in the heart which is brought about by a patent foramen ovale.

**Epidemic Pneumonia.**—Franz Spaet reviews the recent epidemic in Neubrunn in which 63 (13.9 per cent.) persons, out of a total population of 454, were seized with the disease. The first case developed on the 8th of May, and the last on the 7th of July. The majority of the cases (46) were concentrated within three weeks—between May 15 and June 5. Clinically, the type of the disease was severe and the majority of the cases came within the classification of pneumonia known as "typhoid." The author reviews the literature regarding the modes of dissemination of pneumonia, but comes to no definite conclusions regarding the same. There is not doubt that but pneumonia belongs to the so-called contagious diseases, but its mode of dissemination depends upon many local factors and the susceptibility of the population exposed. No bacteriological investigations were conducted in connection with the present investigations, excepting in one instance in which the diplococcus was found to be abundantly present in the sputum.

*French and Italian Journals.*

**The Action of Histone in Diphtheria.**—Mario Flamini says that Carboni has recently made a study of the immunizing action possessed by histone (a pure extract of the cellular juice of tissues) in diphtheria. The author, experimenting on his own account, found that the hydrochlorate of histone obtained from the thymus gland possessed no power against diphtheria, while that taken from other organs had a slight immunizing action against the toxin of this disease and a stronger action against cultures of diphtheria bacilli. This would seem to disprove the theory that the thymus gland possesses a protective action against various infections of childhood.—*Rivista di Clinica Pediatrica*, October, 1903.

**The Treatment of Acute Gastrointestinal Toxic Infections in Children.**—Luigi Concetti holds that the most efficacious treatment consists: (1) In a rigid water diet, giving either pure water or slightly alkaline water, as vichy. This will quench thirst, which is sometimes excessive, supply the fluid in the organism lost by diarrhœa, favor duiresis, and enable the patient to support the absolute fast (2) Thorough evacuation by means of castor oil, calomel, and intestinal lavage. (3) Intestinal antiseptics. (4) Astringents. (5) Medication directed to sustain the heart, kidneys, and nervous system, and to regulate the temperature.—*Rivista di Clinica Pediatrica*, October, 1903.

**Dyspepsia.**—Dr. V., writing of the treatment of dyspepsia, says that the gastric juice of the dog has been

found to be a powerful digestant. Huchard does not hesitate to say that this *gasterine* is to diseases of the stomach what digitalis is to diseases of the heart. It relieves and surely cures. Each tablespoonful contains 1 gram of pepsin, 20 centigrams of HCl, and a good deal of rennin combined with other substances, such as potassium, sodium, and iron. Unfortunately the active dose is very large, one to ten tablespoonfuls with each meal. Moreover, the compound cannot be manufactured, and it can only be hoped that the canine race will be sufficiently numerous to provide for the constantly increasing army of dyspeptics.—*Le Bulletin Médical de Québec*, September, 1903.

**Appendicitis in Women in Relation to Lesions of the Uterus and Appendages.**—M. H. Barnsby reports five cases: (1) An appendix adherent to a hematosalpinx, (2) fixed to an ovarian cyst, (3) to a hydrosalpinx, (4) and (5) to an old pyosalpinx. He concludes that there exists a form of appendicitis secondary to lesions of the appendages. It is chronic plastic in variety, with a tendency to sclerosis. It may be diagnosed by a careful study of intermenstrual or intestinal colic, as distinguished from premenstrual or uterine colic, and by an examination of the upper end of the tumor, which is nearly always high in the pelvis. Treatment, of course, consists in removal of the appendix.—*Gazette de Gynécologie*, September 1, 1903.

**Radiotherapy in the Treatment of Ozæna.**—Adolphe Casassa says that four species of bacilli have been described as specific to ozæna, but so far treatment by antiseptics and by serum therapy has proved valueless. Professor Dionisio has reported the result obtained in six cases by the use of the *x*-ray. There was rapid diminution in the secretion and crusts, and prompt disappearance of the characteristic odor, even in cases that had proved rebellious to all other treatment. More recent reports have brought the number of cases improved up to twenty. The author in his own experiments obtained such excellent results that he can only conclude that radiotherapy is the first and only rational treatment for this offensive and troublesome disease.—*Revue Internationale de Thérapie Physique*, October 1, 1903.

*The Practitioner, October*, 1903.

**The Results of Organotherapy in Addison's Disease.**—Edward W Adams gives the results of an extensive investigation into the subject, and draws the following deductions: (1) There would appear to be a certain class of case of Addison's disease which derives indubitable benefit from the exhibition of some form of suprarenal substance, though in any given case it remains up to now impossible to determine its probable response to the treatment. (2) In any given case of the disease, selected haphazard, the probability obtains that disappointment will follow on the institution of organotherapy: but that probability is very distinctly less than that attaching to any alternative method of treatment at present known. (3) The last word upon the preparation to be used and its method of administration remains yet to be said. The problem seems to be to get a sufficient and continuous dose of the pure and active principle unchanged into the blood stream. Intravenous injection is impracticable.

**The Frequency of Alimentary Glycosuria in the Children of Diabetic Persons.**—Arnold Lorand says that in the majority of the cases observed the children of diabetic persons have inherited a certain defective power of dealing with sugar in their economy. Apparently in such persons the power to assimilate carbohydrates is diminished. All these persons are candidates for diabetes, but it does not necessarily follow that the disease will develop in each case. It can develop itself in persons who are addicted for a long time to an irrational nourishment. Its appearance in the majority of cases is about the thirty-fifth to the fortieth year. Owing to great psychical emotions, it may appear much sooner. We must do our best to defer its advent to a late period, or if it is possible, to prevent its onset altogether. For this purpose we should recommend such persons not to take any great quantity of sweet or amylaceous food. Diabetes is most frequent among classes who eat much meat and amylaceous food simultaneously. Alkaline mineral waters are able to improve the assimilative power for carbohydrates in cases of alimentary glycosuria, and are therefore a useful preventive or at least dilatory agent against diabetes.

**The Causation of Cancer.**—Alex. Theodore Brand says that belief in the infectivity of cancer is founded on clinical facts and logical proofs. Pathological proof is wanting, but that it will be eventually forthcoming is assured. It is only a question of time. No one can deny that cancer is most intensely infectious to the individual, and it cannot be gainsaid that all diseases which are infectious to the individual are capable of communication to others, and are also of external origin, therefore cancer is, and must be, of an infectious nature. Infection undoubtedly differs widely in degrees, and cancer, like tubercle and leprosy, is of a low degree of infectivity, but all the same it *is* infective. The clinical facts are many and convincing. The statistics of cancer districts and houses cannot be explained otherwise than by infection. Over sixty cases of cancer-ä-deux have been reported. Then again cancer has been successfully transferred from man to man, and man to lower animals experimentally. Pending the universal admission of the infectivity of cancer, it should be considered infectious and action taken accordingly.

*Archives of Pediatrics, October*, 1903.

**A Case of Chondrodystrophy Fœtalis.**—J. Park West and W. O. S. Piper report a typical case of this deformity. The main points wherein the child differs from a rachitic and from a normal child are in the length and form of the bones. Compared with a normal child of the same age, this one is 5½ inches shorter from vertex to sole, ½ inch shorter from top of sternum to pubes, ½ inch from vertex to anterior superior spinous process, and 5 inches from anterior superior spinous process to sole. From the acromion to wrist it is 2½ inches shorter, the hand and wrist 1 inch shorter, the thigh 2¾, and the leg 3 inches shorter. The bones are thickened, are distinctly hard, and the anatomical landmarks as distinctly made out as in a thin adult, thus giving one the impression of a small matured bone. The circumference of the child's head is 1 inch greater than that of a normal child, but the diameters are about the same. The shape of the head and the sweating of the head are the only rachitic features present. The size of the face is proportionate to the head, both being large, and not the large head and small face of rickets.

**A Case of Pulmonary Osteoarthropathy.**—Thomas Morgan Rotch and Charles Hunter Dunn report the case of a boy of three years and seven months suffering from continuous cough. He had no night sweats, and had not lost in weight. For nine months previous to entering the hospital the parents had noticed an enlargement of the finger tips. Examination of the lungs showed flatness on percussion over the entire left front of the chest, marked dulness over the back of the left chest, but no absolute flatness. Throughout the left side of the chest—front and back—there was loud bronchial breathing, bronchophony and increased tactile fremitus, with numerous crackling râles. There was a marked enlargement of the tips of the fingers of both hands, giving a flat club-shaped appearance, and this enlargement was also noticeable in the distal phalanges of both great toes. Thoracentesis on the left side showed no fluid, but a solidified lung. A tuberculin test was made twice with negative results. The *x*-ray showed consolidation of the left lung, and, a condition of the distal phalanges which correspond to the description given of pulmonary osteoarthropathy—that is, an enlargement of the entire distal phalanges, involving primarily the bone itself.

**The Prophylactic Use of Diphtheria Antitoxin in School Children.**—Augustus Caillé suggests a new use for antitoxin, by advocating an immunizing injection for young school children once or twice during the school year—for instance, in November and February—with the hope of preventing infection from primary diphtheria or croup; and furthermore with the hope of lessening the mortality of the severe forms of scarlatina and measles, a large percentage of such cases being complicated by diphtheria from the beginning or in the course of the disease. The mortality from scarlet fever plus diphtheria, and measles plus diphtheria is quite high, and the writer is of the opinion, based on clinical experience, that this mortality can be markedly reduced by means of protective inoculations of diphtheria antitoxin. Such prophylactic management will have no effect upon pure and simple scarlatina or measles, but will certainly create more or less immunity as regards grave diphtheritic complications; or, in other words, turn a grave disease into a milder disease. During the past two years the writer has practically followed out this line of thought, has immunized a number of children twice during the school year. No figures are given, for no one can tell what might or might not have happened. It may be stated, however, that not one of the children contracted primary or secondary diphtheria, and in no case was there the least unpleasant or unfavorable reaction after the protecting injection. The parents readily accepted the "protecting vaccination for diphtheria."

# Book Reviews.

A Narrative of Medicine in America. By James Gregory Mumford, M.D., Assistant Visiting Surgeon to the Massachusetts General Hospital, and Instructor of Surgery in Harvard Medical School. Philadelphia and London: J. B. Lippincott Co., 1903.

The author of this charmingly written history strikes the keynote of its real interest when he says in his introductory that the book is a mere narrative of medicine and doctors in colonial and pre-revolutionary times. In following out such a purpose he has taken some of the conspicuous American physicians in each era in their proper sequence to tell the story of their lives and their doings, and through them to illustrate their influence in the development of the medicine of the New World. The history is as interesting as a novel and well calculated to edify the general as well as a medical reader. The leading men of the different periods are the actors who adapt themselves to their surroundings and make the most of their conditions.

American medicine had the smallest possible chances for development during the early part of the sixteenth century. At that time the country was occupied with wars and rumors of wars, and civilization stood merely on guard to protect its interests against the antagonism of unsettled political conditions. What little science there was remained forsakenly in the background. There were then no native-born doctors, none who could receive a proper education in primitive and colonial America. What medical talent there was came from England, France, and Holland with the early colonists. The history of this period covers disastrous smallpox and yellow-fever epidemics, malignant throat affections, and other pestiential invasions with a mortality that can be easily calculated.

Later in the century the American medical man awoke to his privileges and necessities, and we find the most ambitious and affluent of this class taking tedious and perilous journeys to Edinburgh, London, and Paris, and becoming pupils of the great lights of these educational centers. Many of these men came back in time to do valiant service in the Revolutionary War, and take most active parts in shaping the political policies of their periods. Then, also, in the natural course of events, came the establishment of hospitals and medical schools after the European patterns, until the end of the great Civil War, at which period this history stops, America, in little over two centuries of development, took her stand in medicine as she did with other sciences in the first rank of national progress. All this story is so well told, so skilfully interwoven with personal narrative, so judiciously filled with suggestive comments, that the reader follows the author from page to page with the greatest satisfaction and delight.

The individualities of the prominent men that are so identifully and incidentally portrayed, give a striking human interest to the sketches and prove that jealousy, bickering, and malice were as rife then as now. Even quarrels on ethics threatened dissolutions of friendship, and one doctor is said to have declined to meet another in consultation because the latter did not wear a fashionable wig. The account of the discovery of ether makes a very interesting chapter. Morton is rightly given the credit of popularizing anæsthesia, but is justly blamed for the mercenary spirit he displayed in seeking patents. The work, as a whole, is certainly a model of its kind and is destined to take a permanent place not only in medical, but in general literature.

Burdett's Hospitals and Charities, 1903, Being the Year Book of Philanthropy and the Hospital Annual, Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and Cost of the Charities. An Exhaustive Record of Hospital Work for the Year. It Will Also Be Found to Be the Most Useful and Reliable Guide to British, American, and Colonial Hospitals and Asylums, Medical Schools and Colleges, Religious and Benevolent Institutions, Dispensaries, Nursing and Convalescent Institutions. By Sir Henry Burdett, K.C.B., Author of "Hospitals and Asylums of the World;" "Hospitals and the State;" "Pay Hospitals of the World;" "Cottage Hospitals: General, Fever, and Convalescent, with Fifty Beds and Under;" "Helps in Sickness and to Health;" "The Relative Mortality of Large and Small Hospitals," and Editor of "The Hospital." London: The Scientific Press (Limited); New York: Charles C. Scribner's Sons, 1903.

This is the fourteenth issue of the now well-known year book of the hospitals and dispensaries of the English-speaking world. The information contained in the work is invaluable to all interested in institutional work. The fullest treatment is accorded to British hospitals, but those of the colonies and of the United States are by no means slighted, and would receive greater notice were it not for the carelessness of their officers in not furnishing the desired information which only they are able to give. Sir Henry Burdett appears to be somewhat jealous of the medical management of hospitals, and shows a tendency to decry the teaching function of these institutions—which is very foolish, for if students were denied hospital facilities in learning their profession, the hospital patients would later suffer from the defective knowledge of the medical staff. The annual is nevertheless full of valuable statistics, and no one need read the editor's grumblings.

Manual of the Diseases of the Eye. For Students and General Practitioners. By Charles H. May, M.D., Chief of Clinic and Instructor in Ophthalmology, College of Physicians and Surgeons, Medical Department, Columbia University, New York, 1890-93; Ophthalmic Surgeon to the French Hospital, New York; Consulting Ophthalmologist to the Red Cross Hospital, New York; Adjunct Ophthalmic Surgeon to Mt. Sinai Hospital, New York, etc. Third edition. Revised. With 275 original illustrations, including 16 plates, with 36 Colored Figures. New York: William Wood & Company, 1903.

In writing this manual it has undoubtedly been the design of the author to prepare a work especially adapted to the needs of the student and the beginner in ophthalmology. The third edition appears a little less than two years after the second edition, a fact which speaks well for the popularity of the work. The volume is one of 408 pages. It has, apparently, been thoroughly and carefully revised and brought fully up to date. The work is abundantly illustrated in all its parts. There are many plates illustrating the external as well as the internal conditions of the eye. It may be said to the credit of the work that the greater number of the illustrations are original. Much space is devoted to the methods employed for the examination of the eye and to the technique of treatment. In fact, all the points that are of most value to the beginner have been dwelt upon in full. The first three chapters are devoted to the methods of subjective and objective examination of the eye. These are followed by chapters on diseases of the various parts of the eye. A chapter is devoted to the consideration of uveitis, one to intraocular tumors, one to glaucoma, and one to amblyopia and functional diseases of the retina. Then follow chapters in which general optical principles, errors of refraction, disturbances of motility, etc., are considered. The last chapter is one devoted to ocular therapeutics and general rules for operations upon the eye.

Of the many works on ophthalmology which have appeared recently, designed for the use of the student, this is certainly one of the best.

A Handbook of the Diseases of the Eye and Their Treatment. By Henry R. Swanzy, A.M., M.B., F.R.C.S.I., Surgeon to the Royal Victoria Eye and Ear Hospital and Ophthalmic Surgeon to the Adelaide Hospital, Dublin; Ex-President of the Ophthalmological Society of the United Kingdom. Eighth edition. Revised, with 168 Illustrations and Zephyr Card of Holmgren's Tests. Philadelphia: P. Blakiston's Son & Co., 1903.

The popularity of this work is evident from the number of the editions through which it has passed. It is now in its eighth edition and is widely known in America as well as in England. It is a carefully prepared manual of 580 pages. The illustrations are in black and white. There are no plates. The work is not an atlas in any sense. The anatomy and histology of the eye and its appendages are not included in the work. The first three chapters are devoted to the consideration of the properties of lenses, the dioptrics of the normal eye, abnormal refraction and the methods for its correction, and to the ophthalmoscope. The external diseases of the eye, including diseases of the conjunctiva, cornea, lacrymal apparatus and sclera are then considered. The diseases of the interior of the eye are treated of in separate chapters, after which the normal and pathological conditions of the intraocular contents of the orbit are discussed. The last forty-three pages of the text are devoted to a consideration of the effect of the various diseases of the central nervous system on the functions of the eye and the interdependence of the diseases of these parts. An appendix in which the visual requirements for admission into the military, naval, and civil service of England are considered, completes the text. The various operative procedures employed on the eyelids, eyeball, and orbit are especially fully set forth.

The work is carefully prepared and presents the modern views on ophthalmology clearly and concisely. It is a work of average scope, and is well suited to the uses of the student and of those who are engaged in the practice of ophthalmology to whatever extent.

## NEW YORK STATE MEDICAL ASSOCIATION.

*Twentieth Annual Meeting, Held in New York City, October 19-22, 1903.*

(Continued from Page 680.)

*Thursday, October 22—Fourth Day.*

**Diphtheria in the Country; Its Diagnosis and Management.**—Dr. J. R. STURTEVANT of Theresa read a paper with this title. He said that while the State had provided for gratuitous examination of suspected cases, the delay in receiving the report of the bacteriological examination was too great to admit of this plan proving very useful in the rural districts. An instance was cited of an outbreak of diphtheria apparently traceable to the fact that chickens had had free access to a dwelling house, and the author expressed the opinion that there was abundant reason to believe that the open cesspool, so often seen at the doors of farm houses, was a fruitful source of diphtheria. It was the duty of the country physician to have diphtheria antitoxin at hand at all times, in order that precious time might not be lost when a case of diphtheria was encountered. However, he was not a believer in large doses, having obtained perfectly satisfactory results from doses of 1,500 units.

Dr. JAMES J. WALSH called attention to the fact, proved by accurate records. that those engaged in work on the sewage farms and in the sewers of Berlin and London were no more liable than the rest of the population to specific diseases, and especially to specific intestinal diseases, such as typhoid fever and forms of dysentery. They were, however, prone to develop the non-specific diseases of the throat, from which it might be inferred that the emanations from cesspools and sewers were apt to cause pathological conditions of the throat upon which the diphtheria germ might very easily be engrafted. Perhaps the most interesting mystery to-day in pathology was as to the origin of the pathogenic bacilli, their habitat and their life history outside of the human body. Certain it was that a good many of the domestic animals did carry some forms of bacilli.

Dr. J. ORLEY STRANAHAN of Rome said that he had been unable to obtain any results from such small doses of diphtheria antitoxin as 1,500 units A case was mentioned in which 3,000 units were given every six hours for five doses, and that no decided improvement had been noted until shortly after the fifth dose. He had made use of various preparations of antitoxin, and had noted very little difference in them.

Dr. DELANCEY ROCHESTER said that he had had a large experience with diphtheria in the contagious departments of two hospitals in Buffalo, and had learned not to give less than 4,000 units for the initial dose. He had given to infants up to one year of age 5,000 units, and had repeated this in three hours, and since he had been using diphtheria antitoxin he had not lost a case of diphtheria.

Dr. WILLIAM B. ULRICH of Chester, Pa., recalled the fact that up to 1859 diphtheria was an unknown disease in this country, and stated that from his experience in the treatment of this disease prior to the introduction of antitoxin he felt justified in urging strongly the claims of *ad libitum* doses of chlorate of potassium and tincture of the chloride of iron in cases of diphtheria when antitoxin could not be procured—a not infrequent occurrence in many country places because no provision was made for the gratuitous distribution of this great remedy to those who were unable to purchase it.

Dr. Sturtevant replied that New York State supplied antitoxin to those who could not afford to purchase it, but that others must purchase this remedy through the usual channels. His dosage was based entirely upon a airly large personal experience.

**Some Features of the Epileptic Attack.**—Dr. B. ONUF of Sonyea was the author of this paper. He said there was no single symptom that could be called characteristic of epilepsy, and it was only by familiarity with the great variety of forms in which the disease might show itself that one could arrive at a correct diagnosis. Of the first importance was personal observation of the attack. It was now generally accepted that the epileptic cry was not one of fear, but was the result of spasm of the muscles driving the air through the contracted glottis. It was not a shrill cry, as many supposed, but a low, tremulous groan In the epileptic the pupil was often, but not always, immobile. The degree of dilatation gave a fair measure of the severity of the attack, but was subject to certain exceptions. Extreme contraction of the pupil was sometimes observed at the very beginning of the attack. At the commencement of the stertorous stage the pupils were apt to be moderately contracted. Half of the attacks of *grand mal* began with an aura; the face was pale, the eyes open and turned to one side and the whole body was rigid The arms were thrown out from the trunk, the fingers were clenched and the legs and feet were extended. After fifteen or twenty seconds, the face became livid, and gradually the stage of clonic spasm set in The face and eye muscles then twitched, the saliva collected in the mouth and was often stained with blood because of biting the tongue. While the foregoing was the classical description, there were some exceptions. At the beginning of the clonic stage the head might be drawn to one side, and at the end of this stage be drawn to the opposite side. In many cases the head was directed forward. The eyes were not always turned upward or to one side, but might simply be staring. The upper extremities were more frequently flexed than extended. Extension of the legs and feet was by no means the rule. The point to be particularly noted was the asymmetry of the postures assumed. The determination of the state of consciousness during the epileptic attack was often very difficult. If the prick of a pin caused the patient not only to withdraw the part, but to replace it in another place this was evidence of a certain amount of cerebral activity. Sometimes the existence of consciousness would be shown by the patient's recollection of certain features of the seizure. The study of the tendon reflexes had not been hitherto very thorough. In his own experience they had been more frequently exaggerated than diminished.

**A Report of Twenty-five Prostatectomies.**—Dr. PARKE SYMS made this report and presented the specimens. He said that in sixteen of the patients catheter life had already begun; in thirteen there was complete retention, and in one case incontinence of urine. Of the twenty-five cases one died. Two of the patients who survived appeared had permanent incontinence of urine. Of the whole series there were practically twenty cures. In seven cases there was epididymitis occurring sooner or later after the operation. It was not the size of the prostate but its effect on the urethra that should decide the question of operation. He believed every case of prostatic obstruction with infection of the bladder would ultimately terminate fatally without operation. His first twenty-three operations were done without a death. The principal danger connected with the operation was from the anæsthetic.

Dr. GOODFELLOW of San Francisco said that since 18[illegible] he had done about ninety prostatectomies. The cases for operation were those presenting urinary obstruction. The operation which he employed was the old median lithotomy operation, and by pressure over the pubes he found that the prostate could be easily reached and enucleated through the perineum. In order to eliminate the danger from the use of ether and chloroform or ether he had during the past two years substituted spinal cocainization. Epididymitis not infrequently followed the operation, but since he had adopted the rule of refraining as far as possible from instrumentation, both before and after the operation, he had found this com-

plication of rare occurrence. There was, as a rule, almost no hemorrhage in the perineal operation. He had had no case of permanent incontinence of urine, nor of fistula lasting longer than a few months. He had only met with one case of complete atony of the bladder, and that quite recently.

Dr. HENRY ROTH of New York said that he had observed almost all of the twenty-five cases reported by Dr. Syms. It was worthy of note that the mortality in this series of was only 4 per cent., whereas the rate for prostatectomies as done some years ago was generally conceded to be 30 or 40 per cent. It was probable that a better understanding of the capabilities of perineal prostatectomy and an earlier resort to this operation would still further reduce the death rate. The general condition rather than the actual age of the patient should be considered in deciding upon the operation.

Dr. Syms said that he had only tried spinal anæsthesia in one case, and with such terrifying consequences that he had not been disposed to give it a further trial.

**Knowledge of the Eye that Is of Use to the General Practitioner.**—Dr. S. BUSBY ALLEN of New York read a paper with this title. He pointed out the disastrous results arising from a failure to detect acute glaucoma, and the ease with which such oversights could be avoided by noting the tension of the eye. In the chronic forms of glaucoma the general practitioner was more excusable if he failed to detect the true condition, for a diagnosis was often difficult. In 30 per cent. of cases of tabes certain paralyses of the eye muscles were observed. Progressive loss of vision, and particularly a narrowing of the field, were also observed, and often long before the appearance of other symptoms. At first, only one eye would be affected. The most usual paralysis preceding tabes was that of the sixth nerve, producing diplopia. Not infrequently ptosis was also present. The onset and steady increase of presbyopia at an unusually early age should excite suspicion of diabetes. Less frequently there was a partial paralysis of the sixth or fourth nerve, giving rise to diplopia, and there might be complete paralysis of all the ocular muscles. These paralyses might occur both in mild and severe forms of diabetes. Cataract was not an uncommon result of this disease. Inequality of the size of the pupils was always a matter of serious import, and the history of gradual failure of the sight should always arrest attention. In acute parenchymatous nephritis there was a sudden partial or total loss of vision, dependent upon what was called uræmic amaurosis. Toxic amaurosis resulting from various poisons should be borne in mind.

Dr. FRANK W. HIGGINS of Cortland made an earnest plea for the more common use of the ophthalmoscope by the general practitioner, believing that in this way many serious errors would be avoided, and that it was better to recognize the existence of some disease of the eye, and refer the case if necessary to a specialist than to let such cases go entirely unrecognized. Expense was no longer a bar to the use of this instrument.

**The Early Diagnosis of Tuberculosis.**—Dr. JAMES J. WALSH of New York presented this paper. He pointed out that despite a knowledge of the contagious nature of tuberculosis physicians, as a rule, failed to make the same searching inquiry as to the source of infection that they would in other contagious diseases. It was safe to say that a pulse above 90, in the absence of excitement, pointed to some chronic infection, and that the toxin of tuberculosis usually disturbed the pulse a long time before the temperature was affected. To determine variations of temperature the temperature should be taken before 8 A.M., about noon, and again about 6 P.M. While the normal temperature was stated to be 98.4° F., the morning temperature in healthy individuals was sometimes 97.5°, and the evening temperature might be 99°. If, however, there were more than a daily variation of a degree and a half it was probable that there was some infection present. It should always be remembered that a morning temperature of 98.5° F. was a degree or more above the normal morning temperature of many persons, and that in such instances it would point to a slight rise of temperature at that time. There was apt to be an extensive consolidation, and often even a secondary infection before tubercle bacilli appeared in the sputa. The posterior portion of the apex was the first part usually affected.

Dr. DELANCEY ROCHESTER said that in some instances it was necessary to take the temperature at short intervals. For example, he recalled a case in which, on taking the temperature three times a day, the variation was not as much as one degree. Feeling certain that tuberculosis was present he insisted on having the temperature taken every two hours from 6 A.M. to 10 P.M. for several days, with the result that it was then discovered that the maximum temperature occurred between eight and ten o'clock in the evening, instead of between two and six in the afternoon as was usually the case, and that there was a total daily variation of two degrees and a half. The morning temperature was often as low as 96 or 97° F. The pulse certainly afforded a clue, but he was of the opinion that careful percussion was even more useful, giving a change in pitch at a time when other methods of physical examination yielded only negative results, even before prolonged and rough breathing could be heard. The physical signs of early tuberculosis were often obtained not only at the clavicle, but above the scapula, often in the upper portion of the scapular region. The tuberculin test was a most important means of confirming the diagnosis in doubtful cases.

Dr. S. A. KNOPF of New York said that sometimes when it was not practicable to take the temperature frequently he had it taken before and after exercise. What was known as the sign of Muller was often an important diagnostic aid. Patients with consolidated lung when talking loudly were often conscious of a vibration in the solidified area. With a little care the examiner could discover this by placing his hand on the chest and telling the patient to take a deep inspiration and then make a humming sound. It was important to know not only the patient's occupation, but its exact nature and requirements. He had known of many cases in which tuberculin had reacted in chlorotic girls, in actinomycosis and in syphilis; but, worst of all, he had known an injection of tuberculin to cause a generalization of the disease; hence this test was both uncertain and dangerous.

**Treatment of Septic Affections by Intravenous Injections of Soluble Silver.**—Dr. GEORGE TUCKER HARRISON of New York read this paper. He said that some years ago Credé had brought forward collargol, a non-poisonous bactericidal and soluble colloidal salt of silver, and had recommended its use in the form of a 15-per-cent. ointment in cases of sepsis. The speaker's attention had first been directed to it last June by a paper read in January, 1903, by Hermann Schmidt of Dresden. It was at present found in the market in the form of glistening scales and granules, which dissolve readily in water in the proportion of one in ten. A concentrated solution was quite stable. The injection must be made very slowly and, of course, under aseptic precautions. He personally made use of a five-per-cent. solution, so that only a small quantity of solution need be injected. He found that the temperature and pulse gave only incomplete pictures of the course of the disease after collargol injections, for this remedy exerted a beneficent influence upon the nervous system and upon the general condition. The good effect was observed in four to six hours in the subsidence of the nervous phenomena, the return of the appetite, and in increased activity of the bowels. The pulse and temperature were not affected quite so rapidly, although sometimes one injection was sufficient to effect a cure. As many as twenty injections had been given by Schmidt in one case, but Dr. Harrison had not found it necessary to

use in any case more than seven injections. The speaker said that there had been a sufficient amount of clinical material collected to demonstrate that this treatment was a therapeutic resource of the highest order in the treatment of septic affections, and his own experience confirmed this view.

**Peculiar Symptoms Following a Radical Operation on the Ear.**—Dr. GEORGE F. COTT of Buffalo reported this case, presenting the patient, a lady physician. There was a history of long standing otorrhœa at the time that a mastoid operation became necessary. Following the operation on May 12 there was a zigzag temperature curve lasting until June 6, together with symptoms pointing to sinus phlebitis and thrombosis. Several examinations of the blood and urine were made with negative result. After some delay the second operation was done, and although the patient had apparently recovered, she still had a more or less marked febrile movement. At the time of the urgent symptoms it was probable that she was suffering from a localised meningitis.

**Acute and Chronic Cholecystitis.**—Dr. J. H. MUSSER of Philadelphia, Pa., presented this paper, but for lack of time, confined his remarks to acute cholecystitis. He expressed the belief that cholecystitis was a primary condition and that gallstones developed secondarily, in consequence of the infection of the biliary passages, and that when gallstones had formed, infection arose, because the presence of the stones led to the formation of an infection itrium. He considered the primary form only. From his own personal experience and from a study of the autopsy records of the Philadelphia and Presbyterian hospitals, he was sure that cholecystitis was a very common disease. Notwithstanding the careful investigations of Herter, he believed that gallstones were almost always secondary to cholecystitis; hence cholecystitis must be a common disease, because all were familiar with the frequency with which these stones were found. He believed many of the so-called cases of relapse in typhoid fever were due to cholecystitis, because he had seen a few cases that seemed to support this view. The cases of cholecystitis were divided into the mild, the severe, and the gangrenous forms. The clinical course of the disease bore a decided resemblance to that of appendicitis. The mild cases were often so mild as to escape recognition. He hoped the day was rapidly approaching when catarrhal jaundice could be eliminated as an entity. Pain and tenderness were the most common symptoms of cholecystitis, being present in 95 per cent. of the cases. The pain was sometimes referred to the epigastrium or radiated to the right shoulder. In the gangrenous form there was pain with a sense of distention at the very outset, but, just as in appendicitis, the pain quickly disappeared coincidentally with the occurrence of gangrene. At this time rigidity would persist, and there would be a chill or some evidence of shock. In 8 per cent. of the primary cases a tumor was present, and was almost always situated in the region of the gallbladder; but occasionally the tumor was lower down, especially when there had been long-standing gallstone disease, or when there was displacement of the liver. There was usually some fever, even in mild cases; in the more severe forms there was a septic temperature. In typhoid cholecystitis nausea and vomiting were usually absent; in the forms due to colon infection nausea and vomiting were more common; they were never, however, such prominent symptoms as in appendicitis. In 60 per cent. of the non-typhoid cases leucocytosis prevailed; in 40 per cent. only of the typhoid cases was leucocytosis observed. Perforating duodenal ulcer gave rise to symptoms similar to those observed in cholecystitis. The differential diagnosis from pancreatitis without hemorrhage was quite difficult. He had collected thirty cases of typhoid cholecystitis in which bacilli were found; forty-eight cases with a history of typhoid, but in which no bacilli were found; twenty in which there were colon or other bacilli and sixteen cases in which the findings were negative. The mortality of cholecystitis was not as high as in appendicitis. He had found that 40 per cent. of all forms of cholecystitis, not operated on, died, whereas only 5 per cent. died when the operation was done in the course of the disease. It should be remembered that many cases of obstruction of the duodenum or of the pylorus had their origin in cholecystitis. Three of the gravest cases of dilatation of the stomach that he had ever met with had this origin. The fact that very grave results followed cholecystitis had early led him to advocate operation and drainage in every case—indeed, he thought it was perfectly justifiable to remove the gall-bladder under these circumstances. Such early operations almost uniformly gave good results. He felt pretty sure that almost all cases of pancreatitis arose from disease of the biliary passages. The interval operation should be urged if there was reason to suppose that cholecystitis was present. It was safe to assume that in 80 per cent. of the cases the result, without operation, would be serious.

Dr. ROBERT T. MORRIS of New York said that one of the most acute cases of primary cholecystitis that he had seen was one in which typhoid fever apparently began at the gall-bladder. There had been no prodromal symptoms, and yet immediately after operation for acute empyema of the gall-bladder the patient passed through a typical course of typhoid fever. There might not be a marked rise of temperature in primary cholecystitis if the infection were caused by the colon bacillus. The symptoms were sometimes such as to suggest appendicitis, probably because the pressure of a distended gall-bladder on the superior mesenteric vein gave rise to congestion of the cæcum, colon, and appendix. He believed acute pancreatitis to be one of the most dangerous of the complications, and one of the best reasons for operating early in such cases of cholecystitis.

Dr. ALEXANDER LAMBERT said that he had seen cases in which it had been almost impossible to distinguish between appendicitis and cholecystitis. In such cases he had been assisted by the position of the tenderness and the radiation of the pain when pressure was made over the appendix and over the region of the gallbladder.

**The Etiology and Pathology of Salpingitis.**—Dr. EDWARD J. ILL of Newark, N. J., discussed this topic. He said that many cases of tubal disease arose from disturbances of the circulation produced by mechanical pressure, causing abnormally large convolutions and retention of secretion. It was highly probable that the normal tube contained no germs. Puerperal and gonorrhœal infection were the chief cause of tubal disease. The uterine end of the tube was rarely closed by adhesions, but rather by swelling of the mucous membrane and kinking of the tube. Extensive destruction of the epithelial lining of the tube was the exception.

**The Surgical Treatment of Salpingitis.**—Dr. HENRY C. COE of New York read this paper, He said that the comparison of appendical to tubal disease was frequently made, but was hardly warranted, although there was quite a similarity between recurrent cases and so-called pachysalpingitis. The well-known fact that gonorrhœal pelvic inflammation was self-limited and that septic inflammation was prone to be diffuse, had led most gynecologists to adopt an expectant plan of treatment during the acute stage of pelvic inflammation. The modern teaching was to operate early, thoroughly, and intelligently as soon as the presence of pus was detected. It is true that one sometimes failed to find the pus at the time of operation without extensive exploration, but such incision usually resulted in determining the evacuation of the abscess at that point. Vaginal incision and drainage of pyosalpinx was an operation the propriety of which was generally recognized. Fluctuation alone had ceased to be regarded as an indication for operation. The careful surgeon would never approach even a supposedly simple case of pelvic abscess without being prepared to open the abdominal cavity if necessary. It was usually held, that if

the purulent accumulation was near the pelvic brim, it was not a suitable case for attack by the vaginal route, but this depended largely upon the special skill of the operator. It was assumed in all these cases that a radical operation would, eventually, become necessary. He doubted the practical value of attempting to disinfect the tube by syringing it out. The practical difficulty in all conservative operations on the tubes was to decide what tissues were healthy and what diseased. Curettement should precede all operations on the tubes. When a radical operation was indicated it was far better to excise the tube and suture the cornu of the uterus than to employ the older method of leaving a stump. The time had passed when the ovary was removed on one side because the tube was diseased. The modern surgeon kept ever in view the remote as well as the immediate results of operation.

**The Non-operative Treatment of Salpingitis.**—Dr. W. TRAVIS GIBB of New York read this paper. He said that in the treatment of simple acute catarrhal salpingitis the less active the therapeutic measures employed, the better for the patient. Antipyretics and analgesics, especially the coat-tar derivatives, were absolutely contraindicated, as pain and fever were the two guides most relied upon in following the course of the disease. It was only when the temperature became elevated that it might become necessary to reduce it. Any marked elevation of temperature accompanied by a chill usually indicated that the salpingitis was no longer simple, and that more active measures were indicated. Curettage was inadvisable in the acute stage of catarrhal salpingitis, and all intrauterine applications were contraindicated at this stage. When infection had become general and the symptoms were those of general infection, the treatment should, ordinarily, be expectant as regards surgical interference. Of course, if general peritonitis should develop, the abdomen should be opened. The pus of an old pysalpinx was seldom entirely absorbed; if the collection were small, the fluid portion might be absorbed, leaving a cheesy mass of infected material. Many cases of chronic salpingitis could be relieved of their symptoms by non-operative treatment, and hence, such treatment should be given a fair trial, as it could not be denied that even a radical surgical operation did not always remove all of the symptoms. The non-operative treatment should consist in every measure that would promote the general health and diminish the pain and tenderness. Morphine and alcoholic stimulants should be avoided. Much good would result from the use of large douches of hotsaline solution and of vaginal tampons. For the latter purpose, a number of cylinders of lamb's wool, about one inch in diameter and two inches long, should be moistened with ichthyol and inserted into the vagina with the patient in the knee-chest position and the parts retracted. The vaginal orifice should not be distended. The tampons should be removed after twenty-four or thirty-six hours.

Dr. WILLIAM M. POLK advocated the more general use of the incision through the posterior cul-de-sac in cases of severe pelvic inflammation, as this procedure was not only often the means of arresting the pathological process, but offered a better chance for the preservation of the affected organs.

Dr. C. BONIFIELD of Cincinnati, Ohio, said that while it was worth while to make an effort to save the ovaries and tubes, our treatment must depend somewhat upon the social condition of the patient. He wished especially to direct attention to the fact that in the treatment of these conditions we had in vevatrum viride a very useful remedy. In cases of acute peritoneal inflammation, with a rapid, thready pulse, it would be found almost invariably that the pulse would improve under the administration of this drug to the point of producing the physiological effect. Ordinarily, the dose should be from eight to fifteen minims, repeated once in eight to twelve hours. He believed that it had a very decided influence in limiting the inflammation. It not only affected the circulation but stimulated the skin, kidneys, and liver, effects which were desirable in the treatment of septic conditions.

Dr. J. RIDDLE GOFFE said that cases in which the fimbriæ of the tube had become inverted and their peritoneal surfaces adherent, he was accustomed to treat by stripping from the uterus toward the end under a douche of saline solution, and then gradually manipulated them with his fingers until the fimbriæ were opened out. Then, with a spray of saline solution he washed out the interior of the tube. In old gonorrhœal cases he did not hesitate to amputate the portion of tube containing the pus, leaving a stump

**Clinical Aspects of Ileocolitis in Children.**—Dr. THOMAS M. ROTCH of Boston presented a paper on this subject. He said that the onset of fermental diarrhœa was often characterized by the toxic symptom of sudden rise of temperature. The color of the discharges was green or greenish-yellow, and the odor excessively offensive. The discharges were generally accompanied by considerable pain and the passage of gas. There were usually not more than a dozen stools in the twenty-four hours, and they were commonly associated with the discharge of mucus. In about 15 per cent. of all cases albuminuria was present, and in about 15 per cent. of the latter casts were also present. The term, ileocolitis, included all the more grave lesions of the intestine, those commonly classed as dysentery. They were usually secondary to the fermental diarrhœas, and sometimes to the acute infectious diseases, especially measles. It was now known that the dysentery bacillus represented a group rather than a single class of cases. The symptoms of ileocolitis were very unsatisfactory for differential diagnosis. The characteristic symptoms were, elevated and continued temperature, frequent small discharges of mucus, blood, pus, and shreds of membrane, sometimes associated with tenesmus, and usually with abdominal tenderness. The urine sometimes contained albumin. Of sixty-one cases of diarrhœa examined last summer in Boston bacteriologically, the bacillus pyocyaneous was present as the apparent cause in two, the streptococcus pyogenes in one, and the Shiga bacillus in ten cases. In the remaining forty-eight cases the sugar-fermenting organisms were chiefly found. A clinical study of these cases showed that the Shiga bacillus cases included a certain proportion of cases usually looked upon as examples of fermental diarrhœa. The Shiga bacillus was found in 16 per cent. of the cases of diarrhœa, and it was apparently a common cause of ileocolitis, although not all of these cases were so produced. We knew as yet of no clinical symptoms which were characteristic of infection with the Shiga bacillus. It had been proved that the Shiga bacillus was not the cause in a number of cases in which the stools contained specks of blood.

**Colon Bacillus Infection of the Female Genitourinary Tract.**—Dr. ALBERT H. ELY of Southampton presented this paper in abstract. The cases reported were divided into three groups, viz., (1) Those occurring before puberty; (2) those occurring between puberty and the menopause, and (3) those occurring after the menopause. He believed many cases of colon infection of this kind passed unrecognized, and that many cases of simple vaginitis and cystitis were accompanied by toxæmias and septicæmias of very severe type, both in children and adults at an age when it would not be expected. He cautioned against the use, without careful observation, of the so-called urinary antiseptics because of the chance of toxic symptoms arising from absorption through denuded surfaces.

Dr. WILLIAM H. PARK said that the more ileocolitis resembled severe dysentery the more the likelihood of finding the dysentery bacillus. It was highly probable that there was a true Shiga bacillus, found almost invariably in typical cases, and that there was a similar

bacillus more like the streptococcus found in the throat.

Dr. L. EMMETT HOLT said that all kinds of lesions were found associated with the Shiga infection, from the mildest to the most severe. The lesions varied with the severity and duration, and not with the nature of the infection. It was very probable that we should find a fairly well-defined group of clinical symptoms invariably associated with Shiga infection, viz., sudden onset, high temperature, and stools containing blood and mucus. In the fermental diarrhœas it was not probable that much good would result from the use of the serum, but in the acute cases with sudden and severe onset there was a good prospect of securing decidedly beneficial effects from the serum treatment.

Dr. JOSEPH E. WINTERS said it seemed to him that in this discussion two totally distinct diseases had been confounded. A fermental diarrhœa was a food disorder; the other was primarily infectious and dangerously contagious, far more so than typhoid fever.

Dr. ROWLAND G. FREEMAN of New York spoke of his hospital experience last summer with diarrhœa in children. Altogether about forty-four cases were found to have the Shiga bacillus, and in the majority of the cases blood and mucus were present in the stools. With the exception of these stools and the persistence of the disease there was nothing especially characteristic about the symptomatology. He believed most of them were cases of true ileocolitis. The mortality was only a trifle higher in the cases that did not receive the serum treatment than in those so treated, but there was some reason to believe that the dosage employed was inadequate.

## AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

*Proceedings of the Sixteenth Annual Meeting, Held in Chicago, Ill., September 22, 23, and 24, 1903.*

(Continued from page 673.)

**Memorial Address.**—Dr. LEWIS S. MCMURTRY of Louisville, Ky., delivered the Memorial Address on Dr. William E. B. Davis, of Birmingham, Ala. Among other things, he said that no man enjoyed a more honorable career; no one had brighter prospects for years of useful and enjoyable service. Much earlier than was customary in the medical profession, he had attained the fruition of his hopes. He was a recognized leader in scientific accomplishments; enjoyed the respect of his professional brethren in a remarkable degree, and possessed a large and devoted *clientele*. He lacked at the time of his death eight months before reaching the age of forty years. His ability, his energy, his incessant activity, his enthusiasm and capacity for concentration of thought and labor had placed him in the line of demonstrated success and authority at an age when the members of the medical profession were usually only beginning to receive merited recognition. Dr. Davis was born at Trussville, Jefferson Co., Ala., November 25, 1863, and was killed instantly by accident at a railway crossing in the city of his home, on February 24, 1903. Dr. McMurtry gave an outline of the character of an earnest, honest, able and intense man, who, dying before the age of forty years, had done the work usually encompassed in a good long life. He was a leader among the members of the profession, respected, trusted, and beloved. His memory would be revered and cherished in his home by the loved ones there, and his name and fame would remain with the people of the city which was his home in his native State. The statesman and soldier left his monument in bronze and stone; the man of wealth in the colossal fortune that perpetuated his name; the author and poet in pages of thought and songs that lived, but Dr. Davis, who had joined the silent majority, he says, had a thousand monuments in the hearts of those who knew his good offices and appreciated his generous character.

**Some of the Sources of the Disappointments of the Surgeon.**—This was the title of the President's Address, delivered by Dr. L. H. DUNNING of Indianapolis, Ind. He said it was not his purpose to present an address filled with pessimistic statements, gloomy forebodings, or records of unhappy failures. There was no more pitiable object than that of an elderly physician or surgeon, who, after having passed a quarter or a half century in successful endeavor in the practice of his calling, in the declining years of his life fell into pessimism or disbelief. To lose hope in one's successful endeavor and faith in the beneficence of one's life work, was heart-breaking. He once knew a surgeon of this sort who, during a splendid career as teacher and practitioner, reached an exalted position, and who, after his powers began to decline, became a skeptic as regards the curative value of medicine and surgery. A few years later found him specializing in the use of a secret remedy, the constituents of which he did not know, and later still he had entirely lost the confidence of his former patrons and became a cynical old man, entirely dependent upon the support of an accomplished daughter, whom he had educated in his prosperous days. From such a fate, and from other unhappy states that must surely come to a surgical doubter or scoffer, said Dr. Dunning, "may we all be delivered." He begged of his listeners not to hear a pessimistic note in his address. The motive that actuated the writer was one of inquiry to the end that the causes of disappointments in surgery might be ascertained, so that in the future they might be avoided He believed in surgery, and practised it because he had faith in its beneficent power and had experienced some of the joy that came with a moderately successful endeavor. It could not be denied, however, that surgeons met with their full share of disappointments. Judging from medical journal reports, one was led to believe that there were not a few of these disappointments in the paralysis following the bloodless operation for the cure of congenital dislocation of the femur. The successful extraction of a cataract from the eye had given promise of restoration of sight to the organ operated upon, yet, when a sufficient time had elapsed it was found that the patient must walk in total darkness the remainder of his days. A woman was racked by pain in the ovaries, which organs were prolapsed and inflamed. They were extirpated under the belief that such procedure would bring to the patient not only relief from suffering, but also restoration of health, so that she might again with joy take up and discharge the duties of life. Alas! This was not infrequently a delusive hope. Former successes led the surgeon to promise himself and his patient restoration to health or relief from fear of recurrence of an ovarian cyst, if it were extirpated. Upon opening the abdomen, a papillomatous cyst with secondary peritoneal involvement was found, and the surgeon knew that his hope must fall. After months of thorough study and experimentation, a surgeon brought forward a new procedure, the execution of which he believed would prove a means of lessening the mortality of some grave operation, or would diminish the risks of recurrence of some malignant lesion. The technique seemed scientific and its execution was accomplished with ease. The profession accepted it; its popularity grew so that in a few short months reports of cases were published in many countries and languages. After a time, when a great number of histories of cases had accumulated, it was found that less good had been accomplished by this means than by former long-used ones. One of the sources of disappointment which he mentioned related to the surgeon and his environments. The most nearly perfect surgeon was one who ordered his life with the utmost care. Nature must have been profuse in her gifts to him; a good constitution, excellent health, superior intellectual and tempora mental endowments, an indomitable will, inflexible purposes and high moral susceptibilities. His training should be for the development of these faculties, together with the special training that

would give him the requisite knowledge and skill to do high-grade special work. Add to this good judgment, self-control and moderation in all things, and we had the essential elements of a successful surgeon. Disappointments in greater or less degree would come to all surgeons, be they ever so successful, for it seemed to be the natural order of things that contrasting or antagonistic elements existed side by side. The man who became despondent and inactive because of this was the weak man. The strong man would endeavor to magnify the good and crush out the evil. He would, in so far as it was possible, remove the ugly and retain the beautiful. The surgeon's hope should be to eliminate every preventable source of failure, and when failures came to make of them task-masters compelling the way to better things.

**The Rational Treatment of Postpartum Infections of the Uterus.**—Dr. D. Tod Gilliam of Columbus, Ohio, said the rational treatment of postpartum infections of the uterus presupposed a knowledge of the infecting agencies, their nature and tendencies, and of the conditions which favored or retarded their entrance into the general system. The bacteria of puerperal infection were the same that took part in other pathological processes of the genital tract, chief among which were the streptococcus, gonococcus, colon bacillus, and the saprophytes. Saprophytic or putrid infection occurred when fetal detritus —fragments of placenta or membranes—had been left in the uterine cavity. It was pernicious only through its products, the toxins, and would cease to do harm so soon as the fetal débris was expelled from the uterine cavity. Both the colon bacillus and the gonococcus were surface germs showing little tendency to penetrate into the depth of tissues or to disseminate through the general system. The streptococcus was the most deadly of germs connected with puerperal infection. It might and did propagate in living tissues. While all the germs were capable of producing invalidism, there was only one, namely the streptococcus, that jeopardized life. This assertion was to be taken in a general sense, as other bacteria had on occasions been the cause of severe or even fatal infection. It became, then, important to distinguish between streptococcus infection, and that of other germs. Unfortunately, there was no sure method, even the microscope sometimes being inefficient or misleading. Clinically, putrid infection was usually characterized by high temperature, low pulse, and foul odor, whereas in streptococcus infection there was no odor in the earlier stages, and the pulse was markedly accelerated. There might be suppression of lochia. The normal death rate for puerperal infection was about one per cent. This was increased in epidemics, which were usually due to streptococcus infection. The death rate from streptococcus infection was about 5 per cent., and these constituted about one-fourth of all cases of puerperal infection. Hence, about 98 or 99 cases out of a hundred should recover, if let alone. A recently delivered uterus was a hotbed for infection, being filled with the juices of disintegration and spilled blood. The mortality would be appalling were it not for the safeguards. These were: (1) Autosterilization of the genital tract; (2) the protective epithelium; (3) the protective leucocytes under the epithelium The germ of Doederlein was the principal agent in sterilizing the genital tract; hence irrigation before or after labor was harmful, because it washed this germ away, and did not entirely rid the tract of pathogenic germs. It was impracticable to clear the uterine cavity of pathogenic germs by curettage or flushing, as many of the germs were ensconced in the depths of the utricular glands, and could not be reached, hence curettage or flushing by opening avenues of infection without getting rid of the pathogenic germs was harmful and dangerous. The epithelium was usually an efficient preventive of germ invasion. The protective leucocytes under the epithelium gave battle to the germs, and unless overwhelmed would prevent their entrance into the general circulation. The normal death rate of puerperal infection was about 1 per cent., but after curettage it amounted to 20 per cent. The sharp curettage was especially dangerous, as it not only failed to remove the germs, but destroyed the protective barriers. As it was impossible to say that streptococcus infection was not present in any case, the only safe way was to eschew the sharp curette entirely in puerperal infection. Curettage was permissible only when there was known to be fetal débris in the uterine cavity, and when there was reason to believe no streptococci were present. For this the finger or dull curette with stiff handle should be used. Flushing, if done at all, should be done with every precaution against infection. The patient should be on a table, under a good light, the vulva and vagina cleansed, the latter with five-per-cent. creolin in liquid green soap, mopped, dried, and retractor introduced; the cervix grasped, drawn down, and steadied with forceps; the cervical canal wiped out with gauze and bits of membrane picked off with forceps. Gently introduce irrigator and flush. If pulse and temperature should drop, repeat daily or oftener, otherwise discontinue. Alcohol might be installed according to Ill's modification of Carosso's method.

**Penetrating and Perforating Gunshot and Stab Wounds of the Abdomen.**—This was the title of a paper presented by Dr. John Young Brown of St. Louis, Mo. The author went fully into the literature of this subject. An analysis showed nine cases of perforating wounds of intestines, with six recoveries and three deaths. Of the deaths, one was due to shock, the injury being so extensive that the patient never reacted. The author's second patient entered the hospital with general peritonitis, and while a perforation was overlooked, it was probable that the result would have been the same if this injury had been repaired. The third patient, he thought, could have been saved. Of the wounds of the liver, five patients in all, four recovered and one died. This patient died three hours after operation from shock, the result of hemorrhage. A patient with wound of the pancreas recovered. To these cases he added eight in which laparotomy was done and no injury to viscera found, making a total of twenty-three cases, with nineteen recoveries and four deaths.

**The Use of the Stem Pessary for Infantile Uteri, Scanty Menstruation, Amenorrhœa, and Dysmenorrhœa.**—Dr. J. Henry Carstens of Detroit, Mich., cited a number of intractable cases of this kind, which were promptly relieved by the stem pessary. The theory was that weak or poorly-developed muscles could only be strengthened by constant exercise. The only way to exercise the uterine muscles was to introduce something into the uterus, and the constant tendency to expel the contents would enlarge the muscles and develop the uterus. It was absolutely essential that no pelvic trouble, either chronic or latent, existed. The diagnosis must be perfect. The use of the stem pessary was valuable in infantile uteri and in atrophy of the uterus. In amenorrhœa, including scanty and irregular menstruation, especially as found in fleshy women, it was also of great value. It might be used with great advantage in simple cases of retroversion in young girls, and cases of stenosis or tortuous uterine canals. He used the Chapman hard rubber pessary, and left it in from six months to two years.

**Tuberculosis of the Female Genitalia and Peritoneum.**—This was the title of a very exhaustive paper conributed by Dr. John B. Murphy of Chicago. The author considered at great length tuberculosis of the vulva, vagina, portio vaginalis externa, cervical canal, fundus uteri, tubes, ovary, pelvic peritoneum, and general peritoneum.

**Movable Kidney with Secondary Cyst Formation, Resembling Ovarian Cyst.**—In a paper on this subject, Dr. Rufus B. Hall of Cincinnati, Ohio, said that until recent years the consensus of opinion of the profession was that

Mo.; *First Vice-President*, Dr. A. B. Miller, Syracuse, N. Y.; *Second Vice-President*, Dr. W. D. Haggard, Nashville, Tenn.; *Secretary*, Dr. Wm. Warren Potter, Buffalo, N. Y., re-elected; *Treasurer*, Dr. X. O. Werder, Pittsburg, Pa.

The determination of the time and place for holding the next annual meeting of the association was left to the Executive Council to decide.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held September 28, 1903.*

CHARLES N. DOWD, M.D., PRESIDENT.

**High-frequency Currents.**—Dr. HENRY G. PIFFARD read a paper on this subject, accompanying it with demonstrations. (See page 681.)

Dr. A. D. ROCKWELL said that physicians were much indebted to Dr. Piffard for exploiting the very original suggestion of our French confrères, as well as for a good many original suggestions of his own. The term high frequency was certainly well applied to both the D'Arsonval and the other current. He also believed it was applicable to the static wave current. The distinguishing characteristic of the high-frequency currents was an absence of sensory and motor effects. D'Arsonval passed his current through the patient and lighted a lamp by having the patient hold the lamp in his hands. The speaker said he was somewhat perplexed at the asserted magnitude or amperage of these high-frequency currents. Magnitude of current was often much needed in electrotherapy. It seemed to him that in the step-up process we obtained high frequency at the expense of magnitude, for all electrical phenomena must obey Ohm's law. For this reason he was inclined to believe these currents to be of insignificant amperage, and that they did not represent, as Dr. Piffard had said, 200 or 300 milliamperes. As much as one hundred years ago certain experimenters described high-frequency currents, but these older investigators did not at that time appreciate the significance of what they had obtained, and so it was left for others to amplify.

Dr. JULIUS RUDISCH said that it seemed very strange that one or more persons, through whom the D'Arsonval current was passing, could light lamps to full incandescence—not as had been done here, merely to redness. The question arose, then, as to whether this lighting of the lamp was at all comparable with the ordinary lighting of the incandescent lamp. The human body was apparently able to tolerate large currents when they acted for only a short time. High-frequency currents had enormous voltage and very small amperage.

Prof. SAMUEL SHELDON of the Brooklyn Polytechnic Institute said that he had been in touch with the work of Dr. Piffard during the past year, and had been impressed, as a physicist, with two things. The first was that when a Holtz machine was employed whose total current at its maximum output was but a fractional part of a milliampere, could produce a current of 300 amperes. He had repeated these experiments with an ordinary Holtz machine and had sent this current through his own body and through a lamp, lighting the latter up to a white heat. He had then measured the current with an ammeter of the Stanley type and had obtained a reading as high as 300 milliamperes. Despite this there was no pain in the body. The reason no higher amperage could be measured was that sparks passed through from the ammeter to its case. This was certainly a surprise to physicists. We were all well acquainted with the theory of resonators in acoustics. The conditions determining the frequency of the vibration were the shape of the cavity and the nature of the orifice. In any closed circuit there was a certain definite period at which electric currents would like to alternate, and the limitations were inductance and capacity. In order that the frequency might be high the inductance and the capacity must be low. The frequency would be determined by these two factors, capacity and inductance. In the particular apparatus exhibited, an impulse of energy, like the blowing of wind against the mouth of an organ pipe—that rapid discharge between the balls of the Holtz machine—was what started the vibrations. The second thing which had impressed the speaker was that the human body could stand 300 milliamperes; personally, he had been unable to stand 20 milliamperes of an ordinary current. It had occurred to him that if a current travelled through the body, it probably did so through the liquids of the body, decomposing them and generating gases in the cells of the body. But, on attempting to accomplish such decomposition, using water, he had found that liquids did not conduct these high-frequency currents; hence the conclusion had been forced upon him that the tissues themselves, and not the fluids of the body, were the means of conducting these currents.

Dr. CLARENCE E. SKINNER of New Haven expressed his appreciation of the work of Dr. Piffard, and corroborated his testimony as to the therapeutic usefulness of these currents.

Dr. WILLIAM J. HERDMAN of Ann Arbor, Mich., also complimented Dr. Piffard on the excellent scientific work he had accomplished. He emphasized the fact that we were entering a new era, one in which attention was being directed to physiological therapeutics, *i.e.* the use of heat, light, ultraviolet light and electricity. These modalities were coming to the front, and largely taking the place of our drugs. We should recognize that these different agents were only different manifestations of one and the same thing. He was of the opinion that fully 80 per cent of what could be accomplished by drug medication could be equally well attained by electric treatment. All of the eliminative activities that we attempted to secure by cathartics could be brought about by means of electricity and leave no deleterious effects. We could not, therefore, ignore these therapeutic actions. In the department of nervous diseases he had for twelve years made use of electricity in some form for the purpose of producing metabolic changes in defective conditions of the system. He had found one of the best ways of producing elimination was by subjecting the person to one of these high frequency high-tension currents. Such an agent had been proved, beyond any question, to increase the output of uric acid and carbon dioxide and to increase the tonicity of the blood vessels. What physicians needed at the present time above all was a clear conception of what they were using. This agency was attracting the attention of humanity, but unfortunately the physicist knew a vast deal more of this wonderful agent than did the physician. We should, therefore, begin with the physics, then take up the physiology, and having established a good groundwork, pursue our investigations in the realm of therapeutics. As to the difference between these low voltages and the low frequency as compared with the higher, the speaker said that when a direct current was interrupted its electromotive force or voltage was changed, and when applied to the body the muscles contracted or the nerves responded by sensation. When the frequency of interruption was increased beyond six or, in some instances, ten thousand the human organism no longer responded. Nevertheless molecular activities were disturbed, as shown by the increased elimination and metabolic activity. Whether or not these currents of high frequency traverse the body we did not as yet know; some were of the opinion that they only passed over the surface of the body; but in any case the physiological effects were positive, and could not be disputed. We should not forget that all of the activities in our organism were capable of being transferred into electrical energy.

Dr. JOSEPH COLLINS said he regretted that his experience with electricity prevented him from agree-

ing with the previous speakers. For the past ten years he had employed currents of both high and low frequency, and n various forms. For the past two years he had tried the hypostatic current, and during the past year the current of D'Arsonval. He had just returned from a trip abroad, during which he had endeavored to study the work of electrotherapeutists there. He had never found electricity as available as a therapeutic agent as, for example, massage, in the treatment of nervous disease, functional or organic, or of general visceral disease. He did not deny, however, that there was a certain field for electrical treatment. His own experience was entirely opposed to that of Dr. Herdman regarding the eliminative action of electricity. He admitted that, following electrical treatment, there might be increased diuresis or diaphoresis, and an increased output of urea or uric acid, but the same result might follow the taking of a cup of coffee. While making these statements, he wished it understood that he was not trying to depreciate electricity, but rather to justify his belief that electricity was not of signal value in therapeutics. He declared that proof was entirely lacking of the statements made in favor of electrotherapy. He had hoped to hear of new applications of electricity of much promise, but he had been disappointed, and with a fairly extensive knowledge of electricity he felt justified in making these statements.

Dr. Piffard, in closing the discussion, said that he thought the demonstration of the lighting of the lamp should be sufficient to show Dr. Rockwell that a current of much more than two or three milliamperes was employed. The lamp could be brought to full incandescence if specially constructed lamps were used, but because of the peculiar insulation employed in our commercial lamps a spark would occur and break the lamps.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held October* 1, 1903.

CHARLES L. DANA, M.D., VICE-PRESIDENT, IN THE CHAIR.

**Predisposition to Tuberculosis.**—Dr. JOHN B. HUBER read this paper. He said that up to very recently it had been contended that only a vulnerability to tuberculosis was transmitted from parents to their offspring. It was a well-defined law of heredity that functional rather than anatomical alterations were transmitted. Insanity and alcoholism were often correlated with tuberculosis. In tuberculous, as in syphilitic subjects, there were usually present degenerated states of the tissues which rendered them an easy prey to bacillary invasion. There was abundant evidence of primary tuberculosis in the bronchial glands, and in almost every part of the body primary tuberculosis was found. The place of deposit, however, was not necessarily the point of entrance of the parasite. The bronchial twigs which supply the apex of the lung were often defective in their structure, and, moreover, there were imperfect expansion and aëration of this portion of the lung, so that it was not surprising that the apex of the lung should be the point of election for the tuberculous process. In infants, abdominal tuberculosis was much more frequent than pulmonary, and at this period of life gastrointestinal diseases were especially frequent. If digestion in the stomach were impaired, the tubercle bacillus might be allowed to pass through the intestine, and from there they would pass into the thoracic duct and would eventually reach the pulmonary circulation by the way of the vena cava. A faulty metabolism played an enormous part in rendering the tissues vulnerable to the invasion of tuberculosis. A deficient circulatory system meant reduced oxidation and tissue starvation, particularly in the lungs. Pulmonary tuberculosis was almost invariably found in persons dying in the course of chronic alcoholism. It was difficult to explain the effects of alcohol, but the bad effects of alcohol in this disease were largely connected with the unhealthy conditions associated with alcoholism. Poverty, with all that it implied, stood in an important etiological relation to tuberculosis. There seemed to be a subtle relation between insanity and tuberculosis. Many of the inmates of insane hospitals apparently free from tuberculosis on admission to those institutions, developed the disease subsequently, and of those entering with the disease already developed, very few recovered. Altitude, temperature, moisture, season, and soil were probably also etiological factors. Among the diseases predisposing to tuberculosis were bronchitis, pneumonia, influenza, the exanthemata, typhoid fever, and diabetes. The speaker was of the opinion that scrofulosis and tuberculosis were not always the same thing. The scrofulous constitution was one upon which the tubercle bacillus was often, but not always, implanted. The Koch bacillus was by no means the only factor to be dealt with in tuberculosis. The antimicrobic drugs which had been given internally with the idea of destroying the bacilli had been generally worse than useless. Our improvement in the treatment of tuberculosis lay, not in the use of any special bactericide, but in our appreciation of hygienic methods.

Dr. W. FREUDENTHAL emphasized the important part played by the upper respiratory tract in the development of general tuberculosis.

Dr. S. A. KNOPF said that in the main he agreed with the reader of the paper. It had been his frequent and sad experience that the children of tuberculous parents were very apt to contract the same disease, and, hence, he could not understand why some writers still insisted that such parents often conferred an immunity upon their offspring. His own view of the question of heredity in this connection was that there was a transmission of physiological poverty. The majority of tuberculous people coming from large families, according to his experience, were not the first-born, but those born when the parents were comparatively old and feeble. The theory had been advanced that predisposition to tuberculosis was partly dependent upon what might be called a demineralization of the blood. The gentleman who had propounded this theory had also recommended that tuberculous persons be given large quantities of common salt, and, in the speaker's experience, this was a valuable suggestion. Whatever might be the explanation, the fact remained that these persons seemed to thrive upon food containing an abundance of salt.

Dr. A. JACOBI said that alcoholism could only be charged with undermining the constitution, and thereby causing some sort of predisposition to microbic invasion, not necessarily only of the tubercle bacillus. Further than this he would not be willing to admit that alcoholism was a predisposing cause of tuberculosis. We had all been taught that serious heart disease and tuberculosis were not often found associated; indeed, there were some facts pointing rather to the probability of heart disease tending to prevent rather than to cause tuberculosis. Bier had shown that by the artificial production of venous obstruction tuberculous joint disease could sometimes be cured. In heart disease there was venous obstruction in the lungs, and this fact probably explained why tuberculosis and heart disease were very seldom associated. When the conformation of the chest was such as to interfere with the free and natural movement of the lungs, there was more apt to be tuberculous involvement. As far back as 1858 Freund called attention to premature synchondrosis of the sternum and ribs in young subjects as being frequently associated with tuberculosis—a fact which should cause no great surprise, because the effect on the chest would be to make it long and narrow and interfere with the action of the lungs. It was not so much poverty as overcrowding that explained the spread of tuberculosis among the poor. It should not be forgotten that in infancy there was a natural predisposition to tuberculous infection, owing partly to the deficiency in bacterial ferments in the blood of infants as compared with what was

found in older children and in adults, and partly to the anatomical condition of the mucous membrane and the deficiencies of the epithelium there. It had been demonstrated that the tubercle bacillus could pass through normal mucous membrane. Only lately a direct connection had been found between the intestinal tract and the submaxillary gland. Thus, the bacilli might be absorbed in the stomach, be carried to the submaxillary gland without any notable ulceration of the intestine having taken place.

Dr. Louis Faugères Bishop said that predisposition was not a positive, but a negative thing. Most of us were immune to tuberculosis, otherwise we would contract that disease, being more or less constantly exposed to it. The loss of this natural immunity might result from a variety of causes, as, for example, alcoholism and pleurisy. The object of treatment should be to re-establish this natural immunity. We could hardly expect to eliminate infection entirely, but it could be brought within such bounds that the system could cope with it.

Dr. Louise G. Robinovitch said that, according to her experience, extending over a period of many years and including a large number of alcoholic cases in a varied hospital practice, she had been unable to find any direct relation between alcoholism and tuberculosis. She took exception to the statements made in the paper that there was any relation between tuberculosis and insanity, and thought there would be found in the literature high authority in support of her contention.

Dr. Max Einhorn said that about fifteen years ago he had examined the gastric juice of children, and had found that it differed considerably from that of adults. Free hydrochloric acid was very rarely found in these young subjects at the period of digestion at which it would be present in abundance in older persons. He mentioned this to suggest that, because of this absence of hydrochloric acid, it might be that the tubercle bacilli were afforded a better opportunity in the infant's stomach for passing through the stomach unharmed.

Dr. Huber closed the discussion. He said that several pathologists had told him that tubercle bacilli were almost never found in the alveoli of the lungs, and that, while particles of dust might be found in the alveoli in cases of anthracosis, this was not common. This fact, therefore, showed the possibility of the tubercle bacilli gaining entrance to the alveoli, even though this was not the usual channel of infection.

## Medical Items.

**Contagious Diseases — Weekly Statement.** — Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 24, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 108 | 7 |
| Diphtheria and croup | 285 | 39 |
| Scarlet fever | 86 | 2 |
| Smallpox | 2 | ... |
| Varicella | 28 | ... |
| Tuberculosis | 322 | 148 |
| Typhoid fever | 90 | 21 |
| Cerebrospinal meningitis | ... | 3 |

**Great Britain's Mortality Statistics.**—The Sixty-second Report of the Registrar-General of the United Kingdom for 1899 gives the death from zymotic diseases at 89,235, or 2,811 per million of population. Tuberculous diseases destroyed 60,659, or 10.4 per cent. of deaths from all causes. Alcoholism caused the death of 2,871, or 112 per million living among males and 70 among females. Cancer and malignant diseases destroyed 26,325 persons, or 829 per million of all ages and both sexes. As to the infant mortality, 163 infants under 1 year of age died in 1899 in every 1,000 of the population in England and Wales. It has increased from 149 in 1871 to 1880 There were 82,103 deaths in lunatic and idiot asylums, or 14.1 per cent. of the total deaths in England and Wales.

**Health Report** — The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 24, 1903:

### SURGICAL INTERFERENCE IN HYPERTROPHIC BILIARY CIRRHOSIS OF THE LIVER.*

BY DR. JULIUS ROSENSTIRN,
SAN FRANCISCO, CAL.
SURGEON TO MT. ZION HOSPITAL.

THE surgical opening of a new side-track for the blood of the portal vein has been performed for the relief of atrophic cirrhosis of the liver with ascites exclusively. Ever since Thomas Lens'[1] first publication, the fixation of the omentum to the peritoneum has been done to alleviate symptoms resulting from hepatic cirrhosis with vascular obstruction, and the consequent accumulation of the ascitic fluid in the peritoneal cavity.

In the first of the two cases I am about to bring before you, an erroneous diagnosis of adenoma of the liver was the reason for the second laparotomy, and when the true nature was discovered the operation of sewing the omentum, gall-bladder, and liver to the parietal peritoneum was made as an ultima ratio experiment only.

In the second case the diagnosis of hypertrophic biliary cirrhosis—Hanot's disease—was considered prior to the surgical interference and the operation planned deliberately and deemed justifiable by the successful issue of the first one.

CASE I.—Mr. Samuel Magnus, a native of Prussia, thirty-nine years old, a salesman, residing in San Francisco, came under my care September 22, 1902. The father died of some unknown lung and liver trouble; the other family history is negative. He is a moderate smoker, and drinks very little.

He had gonnorrhœa when a young man, but no lues. Suffered from hemorrhoids twelve years ago, from inflammation of the bowels eight years ago, and from muscular rheumatism four years ago. About three years ago the patient suffered from headache, constipation, and tenderness and pain over the liver. His stools were not clay-colored, but he passed a little blood with the fæces. He has been more or less jaundiced since that time and did not feel well since. He never had any symptoms of intermittent fever.

The present aggravation of his illness began two months ago, when he suffered from diarrhœa and passed a great deal of slimy mucus with his stool, became more jaundiced again, had poor appetite, and suffered from cramp-like pains over the right hypochondriac and iliac regions. The pain has increased in violence and is particularly severe between the angle of the costal arch and the umbilicus.

The examination shows his eyes to react normally to light and accommodation and the conjunctivæ of a deep yellow color.

The thoracic organs are normal. There is a pronounced tenderness on pressure below the right costal arch and over the appendix, and a marked bulging in the right hypochondriac region.

On palpation the right rectus is found more resistent than the left. A hard swelling in the abdomen can be mapped out, reaching down into the right hypochondrium to near the level of the umbilicus. The upper border of the liver-dulness extends along the superior edge of the sixth rib, its lower border in the mammary line is within one finger's breadth of the umbilicus. The surface of the swelling feels smooth and even. The spleen extends from the seventh to tenth ribs and is easily palpable. Temperature not over 100°, pulse between 70–90.

Diagnosis, chronic appendicitis and enlargement of the liver, probably due to gallstones or some obstruction in the gall-bladder or biliary ducts.

On September 22 the enlarged, inflamed, and adherent appendix was removed by the usual incision parallel to and about 3 cm. to the median line from Poupart's ligament. It had been the intention to extend the incision to the liver and remedy what would be found amiss there, but the patient did so badly during the operation, that it was decided to postpone it. Palpation of the liver at the time of the appendectomy showed it enlarged, especially the right lobe, which could be felt well down below the border of the ribs near the line of the umbilicus. A rather hard large growth, about the size of a large walnut, was found in the lower part of the right lobe. The gall-bladder was found somewhat enlarged, but no stones were palpable. The edge of the spleen could be felt below the margin of the ribs and seemed to be harder than normal. A diagnosis of adenoma of the liver was made.

The pain and tenderness in the right iliac fossa passed off after an uninterrupted recovery from the operation, but the pain and tenderness over the liver still continued, and the patient did not improve much.

On November 4, under chloroform narcosis, an incision was made along the outer edge of the right rectus, commencing at the margin of the ribs and going down 10–12 cm. In incising the peritoneum a small serous pseudocyst is opened and about one teaspoonful of clear watery fluid evacuated.

There were a few light transparent adhesive bands with delicate vessels between parietal and visceral peritoneum over the liver and gall-bladder. The latter was slightly enlarged, about the size of a small plum, rather yellowish-gray in color. Its contents could be easily expressed. There were no stones either in the gall-bladder or in the ducts.

The liver showed a yellowish-red color and a nodular surface, was much enlarged, reaching nearly to the level of the umbilicus, felt much harder than normal and had, in the middle of the right lobe, a little below the edge of the ribs, a hard nodule the size of a large walnut. There were several smaller nodules about the size of a hazelnut toward the left lobe.

The gastroepiploic veins along the large curvature of the stomach and in the omentum were much dilated. The spleen could be felt two or three fingers' breadths below the left costal arch.

The omentum was brought into the lower part of the wound and sewed for the extent of 4 or 5 cm

*Read before the California State Medical Society, at the annual meeting at Santa Barbara in April, 1903.

to the parietal peritoneum, so that the latter closed over it.

In the further course of sutures the gall-bladder with its fundus and the liver surface were taken in. In pulling the gall-bladder forward a small superficial tear occurred at its posterior attachment to the liver, and a profuse venous hemorrhage resulted.

An iodoform gauze strip was packed between the gall-bladder and the liver and the wound united around the strip with interrupted layers of chromicized catgut sutures. The skin was united with interrupted silk-worm gut, covered by silver-leaf dressing, and the patient was put to bed. At the end of three days the strip was removed and the remaining opening closed with three interrupted silk-worm gut sutures. The patient went on to an uninterrupted recovery. The stitches were removed on the tenth day. On his leaving the hospital, January 8, the pain and tenderness had entirely disappeared as well as the jaundice, and the liver boundaries were as follows: the upper border coincided in the parasternal line with the upper border of the sixth rib; the lower border was found at the free margin of the ribs in the mammary line. The spleen was still palpable, and no appreciable change in area of dulness was noticeable.

I was fortunate enough to secure his presence here (April 23, 1903), and you can verify by his excellent appearance the continuance of his improvement. He assures us that he never felt better in his life. He has been working steadily for the last three months and has gained about twenty pounds in weight. An examination will show you that the liver does not exceed now the normal boundaries while the spleen is still palpable.

Case II.—My second patient, Mr. Joseph Biber, a native of Roumania, merchant, thirty-six years old, residing in San Francisco, was admitted to the hospital November 8, 1902. His mother died of pneumonia, sixty-four years old; father is still living at an age of seventy-four years. One sister, when thirty years of age, was operated upon for a tumor of the bowels, no recurrence since the operation, five years ago. He is a moderate drinker of beer and whiskey, but very rarely drank to excess. During childhood he suffered from measles, diphtheria, nasal catarrh and supraorbital headaches, and from his seventh to eleventh years suffered from severe and frequent attacks of diarrhœa. In 1897, after eating pickles, he was taken sick with severe epigastric pain and constant vomiting. The patient was told that he suffered from ptomain poisoning. The attack lasted for two weeks and then passed off, but for the following year the patient suffered from frequent vomiting attacks and loss of appetite and a dull heavy sensation in his right side. About this time the veins of the right leg began to swell. Two years later the patient became slightly jaundiced and his urine very dark; the veins of the right leg also began to dilate. He sought medical aid and felt better periodically, but lost strength. Last year the urine again became dark, the jaundice increased and the patient suffered from a dull heavy pain in the regions of the liver and spleen. There was slight constipation at this time and severe pruritus. At present the patient suffers from loss of appetite, weakness and dull dragging pains in the region of the liver. Respiration, 18; pulse, 68; temperature, 98.2°.

The patient is 5 feet, 4½ inches in height, slightly emaciated, having lost 19 pounds since his sickness began, his skin is yellow, and he shows a deep yellow tinge of the conjunctivæ. The pupils react normally. The tongue is large and indented at the margin by the teeth. The mucous membranes are pale and slightly icteric. Thorax is funnel-shaped, bilateral prominence from the third to the fifth costal cartilages, sternum drawn in. Slight excursion of the chest on respiration. Anteriorly there is a slightly higher pitched note on the right side, extending from the apex to the upper border of the fourth rib; vocal fremitus and resonance slightly increased over high pitch area. Heart apex beat not visible, left border of cardiac dulness 5 cm. laterally from the left sternal line; upper border at costal cartilage, right border about middle of sternum not clearly distinguishable. Heart sounds are diminished in strength over all the valves.

Abdomen: Inspection shows epigastric pulsation and distinct bulging in the right hypochondrium. Palpation reveals a tumor in the right hypochondrium, reaching to near the level of the umbilicus, it moves with respiration, and is intimately connected with the liver, painful on pressure, smooth and nonfluctuant. The upper border of the relative liver dulness commences in the parasternal line at the upper border of the fifth rib, the absolute dulness at the lower border of the sixth rib. The lower edge of the liver in the midaxillary line is at the free border of the ribs, 4 cm. below the costal arch in the mammary and right parasternal lines. There is an excursion of 2 cm. on respiration. The edge of the spleen is easily palpable. The area of splenic dulness extends from the upper border of the sixth rib to the costal margin and anteriorly to a point midway between the mammary line and anterior axillary line. Both legs show varicose veins from the feet up to midways on the thighs. They are more pronounced on the right side.

The patient was put on light saline purgatives, full diet, and general roborant treatment, with rest in bed. There was no improvement. Examination on November 23 showed the lower border of the liver at the level of the umbilicus on a point midway between mammary and right sternal line. The other conditions were similar to those on entrance.

An operation was decided upon and performed on November 24. The incision began at the costal arch, at the outer edge of the right rectus muscle, and followed it in a straight line downward about 12 cm. Division of the fascia and muscle and opening of the peritoneum followed. The liver was much enlarged, extending almost to the umbilicus, distinctly granular, hard to the touch, and of a dark red color with a tinge of yellow. The gall-bladder was about normal in size and of a grayish white, slightly yellowish color. The large bile ducts were free from stones or other obstructions, the bile being easily expressed from the gall-bladder slight adhesions between the gall-bladder and pylorus and duodenum; there was no ascites. The omentum had a light yellowish tinge. The gastroepiploic veins along the greater curvature of the stomach and over the omentum were dilated. The spleen was much enlarged, extending to near the umbilicus, but free from adhesions. The omentum was sewed to the parietal peritoneum in the lower half of the incision with catgut. A very small Mikulicz tampon was introduced, as there was considerable hemorrhage from the easily severed adhesions of the gall-bladder, at its lower posterior surface. The hemorrhage was very profuse, so much so that the intended excision of liver tissue for microscopical examination was abandoned. The upper part of the peritoneal incision was also united with chromicized catgut sutures, which were carried through the gall-bladder and liver tissues. The fascia and muscle were united with interrupted chromicized catgut

sutures, the skin with interrupted silkworm gut. Silver-leaf dressing was applied.

The temperature never rose above 99° F. On the third day the Mikulicz was removed, and wound closed with sutures. Stitches removed on tenth day. Healing by first intention.

At the end of two weeks the patient's appetite improved and the jaundice began gradually to disappear. The liver began to grow smaller. On the date of discharge, January 8, 1903, there was no perceptible icteric tint to the skin, and but a faint yellowish tinge to the conjunctivæ, noticeable only on close examination. The upper line of dulness is the same as before operation. The lower border in mammary line about 2 cm. below the costal margin; from thence it extends outward in a horizontal line to the right sternal border. No appreciable difference was distinguishable in the splenic dulness, though the edge was not so easily palpable. The patient returned on February 15, and examination of the liver and spleen show the same condition as on January 8.

On April 13 he presented himself again at my office and was kindly examined by Dr. Henry Harris, formerly of Johns Hopkins, now assistant professor in clinical diagnosis in Cooper's College, who had also examined him and concurred in the physical and clinical diagnosis previous to the operation.

Dr. Harris dictated the following report of a the patients status: (1) Patient of good color, no sign of jaundice of skin or conjunctivæ. Nutrition is good, patient complains of no discomfort, feels well, complains of constipation, relieved by laxatives. Pulse 96, regular in force and rhythm, fair tension, small volume, artery walls just felt. Chest funnel-shaped. Lungs clear. Heart negative. Back shows no deformity. (2) Abdomen of normal contour; flank and inguinal lines symmetrical. In the right half 4½ cm. from the middle line is a linear scar extending from the costal margin 14½ cm. along the outer edge of the rectus muscle. No hernia. The skin of the abdomen is normal in appearance, there is no jaundice, no dilatation of veins, no protrusion of the navel. No caput medusæ. There are three very small cutaneous angiomata, pinhead in size, all of which are on the right side. Respiratory movements are normal and equal, no peristalsis is seen. Litton's sign present.

On palpation the abdomen is soft. Slight pain complained of on pressure over scar at the level of the navel. The areas adjoining the scar are somewhat thickened, more resistent than on the corresponding parts of the left side.

*Liver.*—No bulging on inspection. Percussion reveals absolute hepatic flatness to begin in the right mammary line at the middle of the sixth rib, extending 1½ cm. below the costal margin. The total vertical extent of hepatic flatness in the right mammary line is 11½ cm., being only about 1½ to 2 cm. or about ½ to ¾ of an inch more than normal. In the midaxillary line the vertical extent is 7½ cm. On deep palpation the edge of the organ is not distinctly felt. There is an impression of a round, descending body at the intersection of the costal margin and the right mammary line. The gall-bladder is not felt. There is considerable thickness in the right rectus adjoining the scar. On auscultatory percussion the lines determined previously by simple percussion are confirmed.

*Spleen.*—Inspection shows a shadow descending in the left hypochondrial and the left lumbar regions. On percussion the lateral borders are indefinite, but the vertical extent in the midaxillary line is 8 cm. On palpation the sharp notched edge of the spleen is distinctly felt, the lowest point reached on deep inspiration is 9 cm. below the costal margin.

*Stomach.*—Not dilated. The lymphatic glands are not enlarged. No hemorrhoids. Marked varicose veins on both legs, extending on the left leg to the knee only, on the right to the upper part of thigh. Patient presented himself again in July, 1903; improvement continues; spleen appears smaller.

Hæmoglobin examinations of both patients have unfortunately been lost, only one of Magnus, taken at the time of his departure from the hospital, has been found. With the exception of but 80 per cent. hæmoglobin, this shows normal conditions. Dr. Walsh, our faithful interne, who made the various blood counts, recollects, as I also do, that the first blood counts before the hepatocystopexiæ showed erythrocytes between 3,000,000 and 4,000,000 and hæmoglobin between 50 and 60 per cent., both conditions being markedly improved afterward.

I have also reason to regret that the severe hemorrhage in the second case prevented me from excising a small specimen of liver tissue for microscopical examination. I must confess that in the first case the idea of excision only occurred to me after the closure of the abdomen, but I doubt now whether I would have risked it at the time, as the hemorrhage was nearly as bad as in the second case.

A confirmation of the macroscopical diagnosis by the microscope is a circumstance devoutly to be wished for, to satisfy the scientific demands of such observations. However, the history and the long duration of the illness in both cases, previous to the operation, their pathologic-anatomical changes at that stage, the excessive hypertrophy with induration of the liver, the enlargement of the spleen, the long standing but variable icterus, the complete absence of ascites and anasarca, do not well admit of any other diagnosis than chronic biliary hypertrophic cirrhosis of the liver.

In view of the facts communicated to you, the question naturally arises how to explain the curative effect of the operation. In atrophic hepatic cirrhosis with accompanying ascites, the portal system being obstructed, the operation is done to open new lines of collateral anastomosis in order to carry off the venous blood from the abdomen. It is a simple physical proposition.

But in this hypertrophic form of liver cirrhosis, Hanot's[2] (or rather Todd's disease, for Todd[3] described it in 1857, as recorded in an abstract of a clinical lecture, and drew attention to the hypertrophic form without ascites), no such obstruction exists.

In Hanot's disease, as you know, the hypertrophic growth of connective tissue does not destroy the mass of the liver-cells proper, their quantity remains undiminished, and although the hypertrophic growth of the new connective tissue is not limited to the interlobular spaces, but penetrates at places into the lobuli between the rows of liver cells, these are left unchanged in quantity and quality, and their trabecular structure is well defined. Within these strands of new connective tissue run the interlobular biliary canals, their walls being thickened by highly cellular connective tissue to twice or three times their normal size. These strands also contain small colonies of very tortuous biliary canaliculi, in places dilated and cyst-like.

The blood vessels, hepatic veins, as well as vena porta and arteries, remain wholly unchanged in this disease. The walls of the smallest branches are not thickened, their lumen perfectly permeable, as demonstrated by artificial injections. Only very late

in the course of the disease the hypertrophy of the connective tissue may involve in some places the walls of blood vessels.

The theory of relief from obstruction in the blood circulation not being admissible here to explain the effect of the operation, we must turn to another, viz., the possibility of neutralization of a toxin furnished by the liver in this disease. We have gained some facts from experiments on animals to support this view.

In 1877 Eck[4] tried to experiment on dogs in which he established a direct anastomosis between the portal vein and the vena cava. Of the eight dogs he operated upon, seven died, only one lived two and a half months and then, with a criminal disregard for the result of scientific investigation, ran off without leaving his address. Hahn[5], with his associates, repeated these experiments in 1893 on sixty dogs, of which only about twenty survived the operation for any length of time. All passed through a period of great excitement, their nature was changed for the worse, they grew vicious and stubborn, and when the survivors partook of animal food it developed a nervous irritation that often terminated fatally. Hahn offered the explanation that the venous intestinal blood acts poisonously on the system, when introduced as freely as a direct anastomosis between the vena cava and vena porta would permit.

As the ammonia salts and carbamates are changed to urea and uric acid in the liver, it has been suggested that a study of the consequences of their direct introduction into the stomach under the new circulatory changes might be of interest. It is, indeed, possible to show that carbamates brought into the stomach of normal dogs had no effect, while the same or smaller quantities in dogs which have been operated upon developed these nervous symptoms which, if the dose does not exceed a certain limit (0.2 gm. per kilo of animal weight) may disappear again.

It is possible that there is in this disease primarily a hypertoxicity of the intestinal blood, which, passing through the liver, causes the new tissue growth around the biliary canaliculi. The liver, especially under these pathological conditions, is unable to cope with the increased toxæmia and to eliminate or neutralize the poison carried there by the blood. It is not unreasonable to assume that, with an obstruction in the biliary canaliculi, such as we know exists anatomically in this disease, and a consequent retention of bile in the liver, even the normal communication between the two blood vessels might prove such a free avenue for toxins to enter directly the cardiac circulation that they could not be successfully fought by the unaided natural antitoxic and eliminative tissue actions, except through a more roundabout circulation. This roundabout circulation may be materially helped by a firm and extensive adhesion between the omentum, gall-bladder, and liver on one side and the parietal peritoneum and the abdominal wall on the other, and a more successful fight may be waged with a smaller supply of highly toxic blood through the usual direct route, another part of that supply going through a circuitous channel, where it is possible that a greater or lesser elimination of its toxic qualities may be effected. We have an analogous condition in the splenic toxin, thought to be the cause of the primary enlargement of the spleen and secondary increase in size of the liver in Banti's disease, in which splenectomy has saved the lives of otherwise doomed victims of this malady.

We cannot very well extirpate the liver, but the success in these two cases encourages me to recommend this comparatively harmless operation for trial in hypertrophic biliary cirrhosis of the liver. I am the last one to shut my eyes to the many weak points of the theory advanced by me for the explanation of the successful results, but unless some one of you offers a better one I feel that you should pardon its defects, nor should they prevent you from trying in suitable cases this surgical procedure for a hitherto irremediable disease.

## FILARIASIS IN PORTO RICO.

By BAILEY K. ASHFORD, M.D.,
CAPTAIN AND ASSISTANT SURGEON, U. S. ARMY.

While at Ponce in 1902-03, with Assistant Surgeon Joseph Goldberger, United States Public Health and Marine Hospital Service, I made an extended study of many cases of filariasis. From the wards of the Tricoche Hospital, a large civil institution of Ponce to which I had access by the courtesy of its chief, Dr. Luis Aguerrevere, I was enabled to obtain abundant material. To these may be added cases seen in the city and in consultation with its physicians. Struck by the decidedly large number of such cases, I was of the belief, from what had been seen, that about 10 per cent. of the people of Ponce were infected.

On change of station to Cayey these observations were furthered by study of the blood of the native soldiers in this post. Nightly a squad of from ten to fifteen men were examined, and not only did I find that thirty men in all were infected but that each company contributed about an equal quota. This number of men examined is insufficient to form a correct idea of the proportion infected here on the island, even without considering the possibility that mosquitos have fomented an epidemic from a few original cases. The latter objection, seems, however, to be not very valid, the personal histories from the lips of these men are true. Such histories, when considered in one or two cases, generally admit of doubt. Certain distinct suspicious attacks of phlebitis, with or without chyluria, and always with swollen and painful inguinal glands, are recounted by nearly all. These attacks in nearly every case preceded their enlistment, and when one considers that the soldier is unwilling to give a history of previous disease which might damage his record and which he himself is personally persuaded is of venereal origin, these histories may be given more credence. It is an additional note that mosquitos are not the pest here that they are in the immediately adjoining town of Cayey, owing to the strenuous efforts of the former post surgeon and commanding officer to rid the post of them as a general means of sanitation.

My conclusion is, therefore, that, broadly speaking, the troops of this command have not been the subject of an increasing epidemic of filariasis, but that those infected with the parasite brought it into the service with them.

It was extremely difficult to get family histories

of the disease, as, while generally willing to acknowledge the existence of " buboes " in themselves, they did not care, naturally enough, to thereby involve their parents or other relatives.

The type was, apparently, in all cases, filaria nocturna.

The method of blood examination was the familiar one described by Patrick Manson in his " Tropical Diseases." The squad of men reported at the hospital at some time between 9 and 10 in the evening, and both a fresh specimen with coverglass and a dry spread one-half by one inch were made on the same slide. Each slide was numbered, and this number corresponded to a number in a record book in which the names were kept. The taking of specimens for fifteen men consumed, on an average, about twenty minutes.

After the specimens had been taken, each fresh specimen, previously ringed with vaselin, was searched for the circulating embryo by the use of a mechanical stage, all of the fields being thoroughly inspected. This was done on the evening on which the blood was first prepared. The next day the dried specimens were stained and a similar procedure practised. The low-power objective and high-power eye-piece were used. The microscope was the excellent new portable instrument of Leitz. Whenever an embryo was found the high-power objective was used to establish, if possible, its species. If in a minute's rapid examination of the fresh specimen no filarial embryoes are seen, a further and more thorough search fails generally to find them. The microscopical examination of filarial blood is, therefore, not tedious and, it may be added, most easy, so much so, that I believe it is the simplest process that I have ever seen in which the use of a microscope is demanded.

A few remarks on the disease as it now prevails in Porto Rico may be of interest:

There have been several physicians on the island who have studied individual cases microscopically, but there have been but very few. The first to diagnose filariasis by the microscope seems to have been Dr. Jimenez Cruz of Caguas, P. R., who states that ten years ago he found the circulating embryoes in the blood. There has been no attempt whatsoever, previous to this paper, to determine the extent of infection among the people at large.

*Elephantiasis.*—The disease elephantiasis is well known here and is relatively frequent. From what I have seen I am persuaded that few who harbor filariasis ever come to this distressing stage. It is surely a fact that certain homes have the unenviable reputation of harboring several elephantiasis subjects. Yabucoa is noticeably full of cases of elephantiasis, as I have had opportunity to prove, and Humacao and Cayey, one a coast town and the other at an altitude of over 1,200 feet, are both but little better.

Clinically it is known as "erysipela," and by some "elephantiasis." Surgically it is the subject of instrumental interference. One of the surgeons in Ponce, Dr. Torrez, has operated many times for the relief of scrotal tumors of enormous size with most excellent results. His experience extends over many years, and he possesses a fine collection of photographs of his cases, taken both before and after treatment.

The chief deformity seen is elephantiasis of the scrotum, next of one lower extremity, generally the foot and ankle, next of one or both legs to the knee. Rare is it to see the penis, female breast, or upper extremity affected. Only one case of lymphatic varix has been seen by the writer. It was on the temple. Some tumors of the scrotum are immense, but the operation seems to be attended with but few fatalities.

The chief operations performed for relief of excessively large elephantiasis of the lower extremity are: (1) Amputation. (2) Ligature of arteries, and (3) Excision of longitudinal strips of skin and subcutaneous tissue.

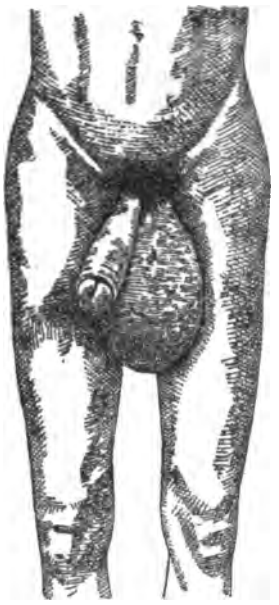
The first generally heals rapidly by first intention if done under aseptic technique. Even if infected there seems to be no special tendency to general septicæmia. It is the best method of treating with a greatly deformed extremity.

The second, ligation of the main artery, is entirely unjustifiable. I have heard of at least one case in which it resulted fatally and published reports bear out this conception of its danger.

The third method, that of excision of strips of skin and subcutaneous tissue. should be further tried, for it is more rational and if done under great precaution against infection it might be of value. One case treated in this manner in Ponce resulted fatally from septicæmia.

The operation done for elephantiasis of the scrotum is, practically, the same as the one described in Manson's work.

The usual procedure is an excision of all affected tissue. This is a most bloody operation as done here, but I have never heard of a death resulting therefrom. The wound seems to heal readily, and if only sound tissue is left no recurrence is probable. I have not observed fistulæ as a sequela of the operation. The great objection to the method employed here is that hæmostasis is imperfect and the patient is greatly weakened by the unnecessarily extreme hemorrhage. There is no valid objection to the figure-of-8 rubber bandage around the waist and the neck of the scrotum, and when it is considered that the size of the vessels in an elephantoid organ are large and troublesome, it is dangerous not to take advantage of this means of controlling hemorrhage, and especially when uncinariasis found in three-quarters of these cases has brought the patient into a severe grade of secondary anæmia.



It is also a matter of practice to open the hydrocele, which practically always exists, by a longitudinal incision, and to cut away a portion sufficient to allow of a close approximation of the walls of the tunica vaginalis to the testicle. The lips of the wound in the tunica are scrupulously sewn up afterward. As a matter of fact this tunica is so thickened in many cases as to be like parchment, and it would seem wiser to cut as much of it away as possible and not try to make a smaller sac by stitching it up again.

The writer has had but two operations for scrotal elephantiasis, one complicated by elephantiasis of the penis, as shown in the accompanying illustration. I removed a large diamond-shaped piece of skin and subcutaneous tissue, including all the affected portion of the scrotum, beginning at the base and underneath the penis and ending at the perineum. Especial care was taken to remove all blubbery subcutaneous tissue with scissors curved on the flat. No Martin's elastic band was available at the time,

so that hæmostasis was checked as rapidly as possible with hæmostatic forceps. But for this the bleeding would have been very profuse. Hot water controlled the oozing well. The tunica vaginalis was opened, the contents, a straw-colored serum, evacuated, and both testicles were examined to verify their condition. They were found to be healthy, but the sac was cut away entirely; the cutaneous flaps made a sufficient covering for the testes by drawing a little on the skin from the thighs. During the entire procedure a sound introduced into the bladder was used to prevent wounding the parenchyma of the penis. Recovery was uneventful and the part is now normal in appearance. Previous to operation the great deformity had prevented coition, and recurring attacks of lymphangitis had rendered steady employment impossible.

The other case was that of a man whom I operated upon here in Cayey. This was a lymph scrotum just passing into elephantoid tissue with frequent elephantoid fevers and a large hydrocele on the left side. The hydrocele was part of the lymphatic area obstructed, but neither were embryoes found in the fluid recovered nor was the parent worm discovered. The liquid found was simply a serum. The curious feature of this case was that embryoes in abundance were found both before and after operation, yet they were not found in this fluid. Although not cured of his filariasis the man's deformity has been removed and thus the object of the operation attained. Not only has the deformity been removed but also tissue which had repeatedly been the seat of a recurring lymphangitis with high fever and much distress.

*Filariasis.*—Fevers of filarial nature without any other noticeable manifestation are not uncommon. This fever is sthenic, very sudden in onset, characterized by chill, high temperature, vomiting, pain in back, abdomen, head, and limbs, and generally terminating in one or two days in a more or less profuse perspiration.

Hence the laity and most of the profession unite in a time-honored tribute to malaria. I was about to make the same error myself in the case of a Porto Rican Sergeant. This man appeared at sick call about 7 A.M. and was admitted to hospital with a high fever, etc., at 8 A.M. the blood examination in all cases of fever was made, when, to my astonishment, a filarial embryo wriggled into view. I searched most carefully for the plasmodium of malaria and failed to find it. Absolutely no enlargement of inguinal glands were perceptible, nor was there any sign of lymphangitis on any part of his body. His abdomen, however, was tender on pressure. No quinine was given and no repetition of his fever occurred. This is but one of several such cases which have since confirmed my belief in this group of symptoms. Here a blood examination is the only clue to the situation.

*Varicose Groin Glands with Fever.*—From the simple fever it is but a step to this form. In Porto Rico the disease is locally known as "secas" or dry buboes. The onset is generally caused by some trivial injury to the lower extremity, sometimes so slight as not to be noticed.

Here the glands of the inguinal regions, and almost always also of the femoral region are enlarged, exceedingly painful, but not tending to suppurate. Occasionally they do suppurate, when the name changes again and "bubon" is the designation applied. It is urged that there is great danger without a blood examination by night, of considering some soldier a venereal subject who has not been the recipient of a venereal infection. Not only this, but it is believed that in the "latent" or chronic forms of venereal disease a combination with filarial disease makes suppuration of the inguinal glands more likely. In fact, from the extensive exposure of many soldiers to the risks of venereal infection the enlisted man is apt to himself consider the matter venereal. These attacks of elephantoid fever with varicose groin glands are very severe at times with much pain, hard chill, high fever, obstinate vomiting, and delirium.

Going a little farther, the name changes again when a red inflamed line extends up the inner side of the leg and thigh. Here there is excessive pain and prostration, the attack lasts longer and fears of erysipelas are entertained with reason.

This is called "phlebitis." The native in the mountains attributes these outward manifestations to a cold he has taken from exposure to rain.

In one such case in Ponce Dr. King, Public Health and Marine Hospital Service, and myself were about to use antistreptoccic serum, as the symptoms were extremely violent. On another occasion, in consultation with several physicians of Ponce, I had the pleasure of seeing a case which was in truth a general septicæmia beginning with a phlebitis of filarial nature. The inguinal glands were hugely enlarged. The man died, but before death the filaria was found in the blood and the streptococcus likewise cultivated therefrom. No autopsy was permitted, most unfortunately.

Lymph scrotum seems to impress itself on all who see much of this disease as the border line between filariasis proper and elephantiasis. It is the strongest rational clinical bond between the two conditions. Here it is generally known as "Hydrocele," with which it is often confounded. Recurring elephantoid fevers are the rule. A physician of Ponce stated to me that on pricking one of the superficial lymphatic enlargements which appear as bullæ on the scrotum a stream of milky fluid shoots forth. Generally a thickening or roughening of the cutis with a characteristic elephantiasis appearance is found at the base of the scrotum, from which focus the whole scrotum often becomes involved. The case cited before is an excellent example of this.

Malarial orchitis has been diagnosed several times in my experience here, and has never failed to show a large number of filarial embryoes in the blood. It seems more rational to consider this filarial orchitis in absence of malarial organisms. Chyluria is rather frequent. I do not know to what cause it is attributed by the laity but the profession realizes its significance. In my only case, a woman, no sthenic symptoms developed, but "secas" and filarial blood left no doubt as to its nature. Urotropin was used after thoroughly washing out the bladder, both measures being entirely prophylactic in nature. It disappeared in about a week. It terrifies the uninstructed not a little. The urine in this case was of a salmon pink color and perfectly opaque. Under the microscope fat droplets and blood with fibrin were abundant. The urine was acid.

Treatment, as far as I know, is fruitless as to prospects of cure and the only means at command are those which alleviate symptoms and prevent a streptococus invasion. I have used methylene blue in doses of 20 grains daily for several months with intervals of rest without effect. Ichthyol ointment (10 to 20 per cent.) seems efficacious in recurrent lymphangitis.

The cases cited below are those of the thirty Porto Rican soldiers in whom I found filaria nocturna. A further report will be made if

any matter of interest is evolved at some future time.

Differential counts of leucocytes to determine the presence extent and periodicity of eosinophilia were not made, for only those who are not infected with uncinariasis should be taken, and this would be a hard factor to exclude, as most of them are infected. I have been convinced that eosinophilia exists not alone from the literature but from personal observation.

It is seen that while not always, perhaps not often, followed by great deformity, still this disease is a most serious menace to the future condition of the host of filaria nocturna. If such subjects are to be admitted to the service the fact of their infection should be noted before enlistment to avoid the inevitable pension claim when doubt arises as to time of onset of symptoms. The use of mosquito bars and the prevention of breeding places for mosquitos, the selection of posts in the open country, with good drainage and remoteness from standing water, are of prime importance, and should be covered by peremptory orders.

Sleeping out of quarters is a most pernicious evil, and when it exists it is at the risk of filarial infection. That Americans on the island, living in crowded towns, are exposed to infection is beyond cavil. As seen by the report below, one Spaniard who had lived but eight years here became heavily infected with filaria.

As to how rapid such infection may be in the presence of the infected mosquito is a question to be decided by a closer knowledge of the disease. Infection in those cases seem to me to be fairly sure but somewhat slow of development. All the foregoing prophylaxis has been practised here, and frequent and rigid inspections have been ordered by the commanding officer of the post, whose interest in the matter has not been less than that of the surgeon.

Cases of filariasis in the mounted battalion of the Porto Rican Provisional Regiment of Infantry:

Case I.—Cook P. S., aged twenty-four years and nine months, born in Manati, P. R., where he lived ten years; lived in Arecibo, San Juan, and Ponce the rest of the time. States that his father and aunt suffered from swelling of one foot and leg with fever. Has received slight injuries on feet and legs, which gave him chill, fever, pain, and a red line on one leg, with swollen and painful inguinal glands. Disease existed prior to enlistment.

Case II.—Private A. D., aged twenty-six years and nine months, born in Yabucoa, where he lived fifteen years; lived in Guayama four years, in Patillas three years, and in Fajardo four to five months. Has had chyluria, and frequently suffered with inguinal adenitis attended by pains, fever, and sweats. His father and brother many times had inguinal adenitis with "hydroceles." His filariasis probably existed prior to enlistment.

Case III.—Private A. L., aged twenty-two years and eleven months; born in Arroyo and has always lived there (this town is the port of Guayama). Has varicose groin glands. History of lymphangitis in left femoral region with chill, fever, pain, etc. Was sick eleven days. Mother has had lymphangitis of leg and chyluria.

Case IV.—Private P. M., aged twenty-nine years, born in Humacao, lived in San Juan the rest of the time. Gives history of repeated fevers with inguinal adenitis. Once a wagon passed over his leg without fracturing it or breaking the skin, when a violent attack of what he described as a lymphangitis ensued. Clear history of chyluria. Disease existed prior to enlistment.

Case V.—Private A. P., aged twenty-two years; born and lived all his life in Humacao. Had many attacks when a child of "secas" with fever and pain. Always had a red line on inner side of thigh in these attacks. Has had several attacks of chyluria. His glands are noticeably swollen and have a softer consistency than that found in other forms of adenitis.

Case VI.—Private J. S., aged twenty-three years, born in Coamo, where he lived all his life, save a short time in San Juan. Has had many attacks of "secas" on slightest injury to the lower extremity, accompanied by fever, pain, and a red line on inner side of thigh. One sister had a foot and leg much swollen. Inguinal and femoral tumors. Disease existed prior to enlistment.

Case VII.—Private G. T., aged twenty-four years; born in Humacao, where he lived all his life. Had many typical attacks of "secas" as above described. Disease existed prior to enlistment.

Case VIII.—Private A. H., aged twenty-four years; born in Humacao, where he lived nine years. From that time he went to sea and served as a sailor in a Spanish mercantile vessel twelve years. No history of "secas."

Case IX.—Private B. F., aged twenty-two years. Has been here in hospital with diagnosis of "acute phlebitis," right saphenous vein, following slight injury to leg at stables. He was twelve days in hospital. Born in Aibonito; lived there ten years; rest of the time in Coamo, Santa Isabela, and Ponce. Had "secas" with usual fever, etc., for the first time when twelve or thirteen years of age. Has thickened lymphatic trunks in region of femoral aperture. Disease existed prior to enlistment.

Case X.—Private J. J. D., aged twenty-four years; born in Aibonito, where he lived during the first decade of his life. Lived in Salinas five months, two and a half years again in Aibonito, Coamo two years, and rest of time in Aibonito. The first attacks of "secas" came on when he was ten years of age. Has had six or seven attacks; all came after some injury to lower extremity, and generally lasted two or three days. Disease existed prior to enlistment.

Case XI.—Sergeant R. B., aged twenty-four years; born in Bayamon, resided there four months and the rest of the time in Aibonito. Had an attack of "secas" once before enlisting. Inguinal and femoral glands enlarged and soft. Probably existed before enlistment.

Case XII.—Corporal L. C., aged twenty-one years, born in San Juan, where he lived twelve years; lived in Santiago, Cuba, six years, and in Ponce three years. Has had high fever with painful "secas" several times.

Case XIII.—Corporal F. L., aged thirty-one years; born in Yauco, where he lived twenty-two years. Has had fever, "secas," etc., since childhood. They occurred once a month on an average. Inguinal glands have a soft, doughy consistence and are enlarged.

Case XIV.—Cook C. M., aged twenty-six years; born in San German, where he lived eight years. The rest of the time he spent in Mayaguez. He received an injury in right inguinal region when a child, which gave him a chill, fever, sweats, and painful "secas." He was ill one month. Again, lately, he had the same kind of an attack, which lasted eight days. Inguinal glands enlarged.

Case XV.—Artificer P. M., aged twenty-eight years; always lived in Mayaguez, where he was born. Many times he has suffered from attacks of "secas."

Case XVI.—Private E. C., aged twenty-five years; born in Juana Diaz, where he resided up to

the time of enlistment. Has had many attacks of "secas." This man was admitted to hospital by me on the 13th of July and was ill seven days here. He had all the symptoms described above under the section "Elephantoid fever with varicose groin glands." The dusky red lines of lymphangitis were very prominent, leading up to the enlarged femoral varicose groin gland. Says he had several of these attacks before, identical in every way with the one in which I saw him and he himself diagnosed his complaint as "secas," which he says is the usual name applied to it in this island.

CASE XVII.—Private V. S., aged twenty-three years; born in Ponce, where he lived sixteen years. Thereafter he lived in Spain two and a half years. Has had typical attacks of "secas" with fever.

CASE XVIII.—Private F. R., aged twenty years; born in Morovis, where he lived sixteen years. Lived in Manati two years. Every now and then had "secas" with fever. Varicose glands of groin very perceptible.

CASE XIX.—Private R. L., aged twenty years; born in Ponce, where he always lived. Had "secas" with fever, etc., while a soldier, but did not report sick. Has never had them before in his life. Possibly contracted disease here.

CASE XX.—Private J. C., aged twenty-one years; born in Juana Diaz, where he lived always. Has often had fever, but no "secas." Has, however, varicose groin glands.

CASE XXI.—Private F. A., aged thirty years; born in Humacao, where he lived ten to twelve years. Is a negro. As a child had "secas" from time to time. Gives suspicious family history.

CASE XXII.—Private S. C., aged twenty-seven years; no history.

CASE XXIII.—Private H. B., aged twenty-one years; born in Ponce, where he always lived. Has had repeated atttacks of "secas" with fever, etc. Glandular enlargements in groin.

CASE XXIV.—Private J. R., aged twenty-four years; no history.

CASE XXV.—Quartermaster Sergeant B. C., aged twenty-four years; born in Ponce, where he always lived. When a child, received a blow on his foot which produced fever, painful "secas," etc.

CASE XXVI.—Corporal L. S., aged twenty-six years; born in Guadalajara, Spain. Came to Porto Rico seven years ago for the first time as a Spanish soldier. Has had, beginning two years after his arrival, typical "secas" and several attacks of chyluria. He is a very intelligent man and states that the disease elephantiasis does not exist in his province in Spain. He says that on reaching the island he allied himself with a woman of this place who had several typical attacks of lymphangitis of the lower extremity.

CASE XXVII.—Private F. Q., aged twenty-three years; born in San German, where he lived sixteen years; the rest of his life he spent in Mayaguez and Aguadilla. Has had blows on his legs causing painful "secas" with chill, fever, and sweats and a red line on the inner side of the thigh. This has occurred many times. Twelve years ago he had chyluria, which gave him a great fright.

CASE XXVIII.—Private V. V., aged twenty-three years; born in Caguas, where he lived five years. Has lived in Cayey since that period. Has had many attacks of "secas" with pain, chill, sweats, and a red line on the inner side of the thigh. Has also had chyluria, which he attributed to drinking too much milk. His mother had one leg chronically swollen with intermittent attacks of erysipelas.

CASE XXIX.—Private S. M., aged twenty-five years; born in San Juan and lived there. Has had typical attacks of "secas."

A summary of these cases disclose the following facts:

1. Twelve per cent. of the mounted battalion of the Porto Rican Provisional Regiment of Infantry present circulating embryos of filaria nocturna.

2. Presumably there is approximately a similar percentage among the people of Porto Rico at large.

3. All but three of these soldiers have presumptive history of filarial disease before entering the service.

4. In five cases there is strong presumptive proof of the disease in the families of these men.

5. All were thoroughly exposed to mosquitos in closely crowded towns before infection.

6. All are young men.

7. Most have been three years in the service without serious illness.

8. They come from all parts of the island.

9. All, save four, have had attacks of inguinal or femoral adenitis with chill, fever, pain, and a red line on the inner aspect of leg and thigh at varying intervals.

10. Six have had chyluria.

---

## TREATMENT OF CANCER OF THE UTERUS.*

BY I. L. WATKINS, M.D.,
MONTGOMERY, ALA.

IN order to discuss, intelligently, the treatment of any pathological lesion, it is necessary to know something of its character and etiology. I am sorry to say that we are yet groping in darkness, so far as the etiology of the disease of cancer is concerned, whether occurring in the genital organs, or elsewhere in the body. This state of things certainly cannot last much longer, when such a large number of masterly intellects are devoting so much time to this subject, with the hope of discovering the pathology of this much-dreaded disease.

It is not my purpose to discuss this unsettled question, because you are all familiar with the various theories, since they have occupied very prominent places in recent medical literature. I desire to say, however, that the question of heredity occupies far too prominent a place with the average medical man in his efforts to eliminate any malignant process, in considering symptoms which point to cancerous conditions. While, in a few isolated cases it would seem that heredity possesses some influence in this direction, still statistics show that only from 15 to 20 per cent, of the cases give any family history of cancer. This is far too small a number to establish that theory. I have frequently been impressed with this fact, when discussing with the family physician the probability of a given case being cancer.

The great gravity of cancer makes it important that an early diagnosis be made. It is inexcusable on the part of any physician to fail to make a thorough investigation when suspicious symptoms arise. If I can sufficiently impress upon you the necessity of this precaution, I will have accomplished the purpose of this paper. It is not an unjust statement for me to make when I say that you are, as general practitioners, family physicians or medical advisers, in a large measure blamable for the high death rate in cancer of the uterus. The surgeon or specialist is, very rarely, the first to be consulted in the beginning of uterine cancer. As a rule, almost without exception, the woman applies to you for advice when she detects a daily loss from the vagina, with the probable loss of

*Read at the annual meeting of the State Medical Association, at Talladega, Ala., 1903.

flesh. What is the result? A little gratuitous advice, which, in fact, is worth nothing, or a prescription is given for an astringent wash and a tonic, with the request to report in a month if not better. I cannot be too emphatic in urging those of you who do family practice, to lay aside all idle thoughts on your part when these women, from forty to sixty years of age, come to you with symptoms characteristic of this malady, and make such investigations as will enable you to say positively that these cases have or have not cancer.

From several years' experience I have found that the average practitioner has excused himself from an early diagnosis on the ground of modesty on the part of the woman. It is my observation that when a woman is confronted with the statement that she probably has cancer, that she will not be long in making up her mind to submit to any intelligent management. I want to say that should one decline after the subject has been thoroughly explained to her, it is due to the fact that in your statement of the case you have attached far too little importance to the symptoms under consideration. The thing that frequently deters the physician, is the fact that he will probably be unable to make a diagnosis after the examination. That should have no influence whatever. If you cannot satisfy yourself that the symptoms are not caused from malignancy, it is your emphatic duty to so state to the patient, and to refer her without delay to some one more familiar with the symptoms. I urge that when these cases fall into your hands, you do not go on treating them for weeks, when there is a shadow of a doubt, and lose just so much valuable time. If you will not, we will be called upon less frequently to shield you from blunders, and to make the common statement, "You have come too late." Out of less than one dozen upon whom I have operated for cancer of the cervix or corpus and who yet survive, not one came with a suspicion that she had cancer.

The treatment of cancer of the uterus, as well as of other parts of the body, is essentially surgical. I come with no new operations for your consideration, but will discuss, in a brief manner, some of the various techniques that are in common practice to-day.

It is interesting to notice the improvements which have occurred in operative procedures during the last twenty-five or thirty years. Along in the seventies Schroeder and his contemporaries either curetted or amputated the cervix, and taught that in the majority of cases this treatment secured a longer life without pain. This treatment, though not radical, was at this time regarded as most rational. Hysterectomy so rarely resulted in recovery that it was condemned on the ground of causing more rapid spread of the trouble. It is not certain that a large number of our cases to-day would not live longer and suffer less if we followed a more conservative plan.

In 1878, with a more accurate knowledge of the manner in which the disease spreads, Freund was induced to try abdominal hysterectomy. With this a new era began, and has, with some modifications, continued until the present. His method was to include the broad ligaments on each side of the uterus in three ligatures, remove the organ, and bring these sutures down through the vaginal opening. This operation never became very popular, because of the large death rate following it. Forced by these results, Czerny revised the old method of colpo- or vaginal hysterectomy. It was customary to scrape away, as nearly as possible, all of the cancerous tissue, and cover the field with healthy mucous membrane. These operations were frequently followed by injuries to the ureters, and ureterovaginal fistula. A distinct advance was made when Pawlik of Prague, in 1888, first introduced the catheter into the ureter before beginning operation. By this method it was easy to locate these organs and thereby prevent injury to them. Strange to say, this preparatory catheterization of the ureters fell into disuse, and nothing more was heard of it until 1892, when Dr. Kelley, unaware of this work of Pawlik, commenced to catheterize the ureters as a routine procedure previous to performing the operation of hysterectomy for carcinoma of the uterus. In 1894 A. Mackenrodt advised the removal of the broad ligaments of the uterus. The method which he favored consisted in a long transverse incision above the symphisis. After separating the recti from the tubic attachments, the peritoneum extending above the bladder is stripped nearly to the umbilicus. The peritoneum is then opened transversely just above its vesical attachments, the round ligaments and ovarian arteries are ligated and divided. the peritoneal flap from the anterior abdominal wall is carried up over the uterus and sutured to the posterior peritoneal membrane. The uterus and part of the vagina are then removed by thermocautery. The extraperitoneal space below is easily drained through the vagina.

In 1895 Dr. Ries of Chicago, going on the theory that carcinoma of any portion of the body spreads along the lymphatics, attempted to apply this idea to operations for the removal of cancerous uteri. At the time his paper was written he had only as a working basis some anatomical researches of himself and a few others. As a result of these investigations he arrived at the conclusion that it must be possible to improve its efficiency by extending the extirpation of tissue not only to the broad ligaments of the uterus, but to the neighboring lymphatics. In May, 1901, in a paper before the State Medical Association of Illinois, he makes the following statement concerning his method of operating: "The operation has been ridiculed, praised, and condemned. One who first shrugged his shoulders when the operation was mentioned to him has become its most ardent advocate. Another who would at first have liked to be its godfather has abandoned it." Up to this time this operation had been restricted to cancer of the cervix, based on the theory that the lymphatic glands which drain the cervix are for the most part located in the broad ligaments, along the internal, external, and common iliac vessels over the obturator foramen, and on the anterior aspect of the sacral bone. The operation is one of great difficulty, and not to be undertaken by any one who is not thoroughly grounded in its technique.

About this same date, Dr. J. G. Clarke of Baltimore devised an operation whereby more of the broad ligament might be removed with the uterus. This is a more practicable operation and has met with greater favor. It necessitates the tying off of the ovarian artery, and dissecting out the uterine artery a short distance from the uterus. The ureters must be located and the broad ligaments ligated close to the pelvic attachment. This operation, though extensive and somewhat similar to that of Ries, does not include the lymphatics beyond what exist in the broad ligaments.

At the meeting of the Southern Surgical and Gynecological Association in Cincinnati in November last, I had the pleasure of listening to a paper by Dr. Chas. P. Noble, on the use of the electrocautery clamp in the

treatment of cancer of the uterus. The doctor referred to the cautery as used by Drs. I. Baker Brown, John Byrne, and A. G. C. Skene. The latter devised a set of electrocautery clamps to be used instead of ligatures, in tying off pedicles in the abdominal cavity. These instruments proved not to be practical and soon fell into disuse. It remained for Dr. John A. Downs of Philadelphia to perfect the technique and to develop a thoroughly practical set of cautery clamps. These Dr. Noble kindly presented to the society. The technique of hysterectomy by the electrocautery clamp method, as given by Dr. Noble, is as follows; in order that I may make no mistake I quote him verbatim: "The operation may be in either the vagina or abdomen. If the operation is begun below, the vaginal connections of the cervix are cut through with the electric cautery knife, and (in cancer of the cervix) the cancerous mass is amputated with the cautery knife without opening the peritoneal cavity, if this can be avoided. Bleeding vessels may be clamped with ordinary forceps, or, if desired, may be sealed with a small-sized cautery clamp. The septic cervix is thus removed, the vagina re-sterilized, and, if desired, packed with gauze. The abdomen is then opened, the bowels packed off as usual, with gauze, and the large sized cautery clamp applied to the broad ligament outside of the ovary. By drawing up on the uterus and pushing down the bladder, the clamps may be made to grasp the tissue up to, and sometimes including, the uterine arteries. If necessary, to avoid its inclusion, the bladder may be previously detached and pushed down. After the clamps are in position any blood is wiped away, and the clamps thoroughly surrounded with gauze to protect other tissues from burning. The current is then turned on for thirty seconds, a forceps is placed toward the uterine end of the broad ligament to prevent reflex hemorrhage after the tissues are separated, and the broad ligament is severed with a knife along the uterine side of the clamp. This step usually takes an additional half minute, during which time the cooking process continues, as the clamps retain their heat for some time. The clamp is then loosened and removed, and the cooked pedicle is allowed to retract. If no ligatures are to be used, great care must be taken not to handle or disturb this pedicle, as security against hemorrhage depends upon adherence to this rule. The opposite broad ligament is now treated in the same manner. This leaves the uterus connected with the broad ligament only by its cervical attachments. The bladder is now detached, and pushed down in the usual way, and the clamps are made to grasp the broad ligaments alongside of the cervix down to the vagina. This portion of the broad ligament is treated in the same way as the upper borders. After the lateral attachments of the uterus have been cooked and severed, there remains only the connection of the uterus to Douglas' pouch to be severed. This can be caught in the clamp and cooked before being divided, and the uterus is then removed." The doctor reports only four cases of hysterectomy for cancer by this method, with three recoveries, the death occurring from an accidental hemorrhage. This number is too small for the basis of a very fixed opinion as to the results of the operation, though it certainly must appeal to the surgeon as possessing some merit. Besides being able to remove more tissue outside of the uterus than by the classical method, the tissues are previously cooked by the cautery clamp—they are, including the lymphatic vessels, sealed even far beyond the line of incision by the cautery knife.

As to the danger of injury to the ureters, subsequent experience by this method will be necessary before it can be discussed.

Every year or so new operations are devised for the cure of cancer of the uterus. This fact is evidence of itself that no very reliable method has yet been discovered. It is very clear that with our present knowledge of the pathology of this disease we must recognize it in its earliest stage, before any marked improvement is made in our statistics.

Some general rule should be laid down for the guidance of surgeons as to whether a case belongs to either one or the other of the classes usually accepted, namely, operable or inoperable cases. Cases should be regarded operable when the disease is mainly confined to the cervix or corpus, and the organ freely movable, and inoperable when there is a perceptible deposit outside, and the organ fixed or immovable. In order to make these distinctions, it is necessary that the patient be examined under an an æsthetic. Even with this care there will frequently be differences among surgeons as to the extent of the lesion.

The prognosis in these cases is always doubtful. It has been truly said, that the treatment of cancer of the uterus is surgery's disgrace. It is the reproach to our art, nay, even to ourselves, that this page should appear year after year in our leading works on surgery. The compilation of statistics of 10 to 20 per cent. recoveries which we so frefrequently see in the books is a delusion and a snare. I assert without fear of successful contradiction that should these statistics be analyzed not more than 3 to 5 per cent. of recoveries would be found. The prognosis in the body is much better than that in the cervix. The only chance for improvement in this lamentable state of affairs lies with the general practitioner. When he sufficiently appreciates this fact and examines every woman who complains of a bloody discharge—which in the near future he certainly will—a much smaller number of inoperable cases will be presented.

---

## INVESTIGATION OF RINDERPEST.

By J. A. GUTHRIE, M.D.,
SURGEON, U. S. NAVY.

DURING my stay in Shanghai, I had an opportunity to visit the cattle yards, a short distance from the city, and became very much interested in the successive means employed for the prevention of "Rinderpest." In the first place, the cattle yards are divided up so that each drove of animals, in various stages of immunization, is separated and kept apart from the others, those which have the severest form of the rinderpest, contracted by the immune procedure, are placed in a covered yard, composed of numberless stalls and capable of containing as many as five hundred head comfortably. One section of this yard is called the "sick ward," and particular pains are taken in the methods used for disinfection of it; all the straw and other material after contamination, is burnt and a liberal quantity of lime is spread over the bloody stools, wherever deposited. Not only is all waste material destroyed by fire, and other means of absolute disinfection resorted to, but scrupulous cleanliness is observed in all matters whether pertaining to the care of the animals or to the appliances of this so-called "sick ward."

Those animals that recover from the inoculation during convalescence are placed in other yards according to the extent of recovery, and finally after they begin to enjoy their meals and take on what flesh and fat was lost during the two weeks of immunization, they are ready for shipment to the Philippine Islands. It may appear to the unpro-

fessional observer that such stringent means are unnecessary, but not so, although as great a percentage as from ten to fifteen die, while undergoing inoculation, the least deviation from the methods employed by the proprietors would result in failure to immunize with sufficient thoroughness to satisfy the United States Government officials.

The rinderpest serum for Chinese cattle is prepared by an expert, and the same veterinarian supplies serum for immunizing the large numbers of carabao that have been recently shipped to the Philippines. At present as many as fifty thousand carabao are being transported from China (at the expense of the United States Government) to make up for the loss in the islands (from the ravages of rinderpest) of this valued beast of burden.

It may seem strange, neverthtless it is a fact, that few people really know what rinderpest is: I have heard it described all the way from foot-rot to a chronic skin eruption, and I myself had been at a loss to describe it, until, on this recent occasion, I was afforded the pleasure of investigating its charactei person. I must say that I was surprised at my discovery, for I found a complaint that corresponds almost exactly with acute dysentery in the human being. The period of incubation is about five days, then the animal's temperature goes up from 100°, gradually increasing as the disease progresses, and sometimes, just before the final collapse and prior to death, the temperature reaches 106° or more. After five days of incubation there is a stage of bloody diarrhœa, and continued elevation of temperature which lasts about one week or ten days, when the climax is reached, and they either get better or die.

None but cloven-footed animals contract the rinderpest, no case, for instance, of a horse, having had the disease is on record. In South Africa many thousand sheep have taken the disease, while, singular as it may seem, none of the sheep in China will take it. Repeated doses of virulent blood have been injected into sheep in Shanghai without producing the slightest trace of the disease; Chinese goats, however, are not immune, the same experiment upon them produces all the characteristic symptoms.

The procedure for inoculation is simple. The animal is placed in bamboo stocks (in the West we should use something else), so that the feet are secure, otherwise in demonstrating his objection to having needles run into his flesh the bullock might naturally delay the process, which usually takes twelve and a half minutes.

Ten cubic centimeters of virulent blood from another animal with the disease in progress, and 50 c.c. of the prepared serum from an immune animal, are then injected into the subcutaneous tissues, just behind the forelegs (well down on the abdomen), and after about twelve and a half minutes the serum and germ-soaked blood begin a battle for supremacy in the system of the unfortunate bovine. Which will win remains to be seen. This inoculation is repeated in five days, sometimes in less time, and occasionally two or three extra injections are needed, depending on the animal's condition, then the amount injected, either of serum or of infected blood, according to circumstances, is increased. If the temperature rises markedly, only serum is used in the second injection, and this is decreased in amount for the subsequent injections.

It is to be hoped that by continuous inoculations and perseverance on the part of Government employees as well as private firms, at some time in the future a breed of cattle will be developed that shall be immune from birth, thereby removing one of the greatest curses the Filipinos have to contend with at present. Let us trust that the honest work of honest men may continue in this direction, and that science may soon be blessed with further discoveries for eradicating this fearful pest. There should be a most stringent law, as stringently carried out, to the effect that no animal, whatsoever, which is subject to the contagion, should be allowed within our recent possessions, the Philippines, and, moreover, those already there should be inspected by competent veterinarians, employed and guaranteed by the United States Government, otherwise the pest will never be entirely eradicated from these islands.

---

## SOME PRACTICAL POINTS TAUGHT BY THE DISCOVERY OF B. DYSENTERIÆ IN THE STOOLS OF INFANTS SUFFERING FROM SUMMER DIARRHŒA.

By LOUIS M. WARFIELD, A.B., M.D.,
SAVANNAH, GA.

In 1898 there was published in the *Centralblatt für Bakteriologie* the discovery of the cause of acute epidemic tropical dysentery. Shiga of Japan announced that he had found a bacillus allied to the colon-typhoid group in cases of dysentery occurring in the Japanese troops, and moreover that the serum of patients suffering from the disease agglutinated the bacilli in relatively high dilutions. The bacilli obtained from one patient not only were agglutinated by the serum of the patient himself, but also by the sera of other patients, presenting the clinical symptoms of dysentery. Confirmation of this discovery was not slow in coming forward. Kruse in Germany and Flexner in the Philippine Islands both found bacilli like those described by Shiga in the stools and at autopsy in patients with dysentery.

There were, however, certain minor differences in these several strains of bacilli which need not here be discussed. Suffice it to say that the most recent work goes to show that these various strains of bacilli are only very slight modifications, due no doubt to differences of environment, of one and the same organism. The discovery of the same bacillus in such widely separated regions led to the belief that the distribution of the organism must be very general, and various observers set to work to examine carefully into the epidemics of dysentery occurring in asylums and almshouses not only abroad but also in this country.

In 1901 Vedder and Duval succeeded in isolating the B. dysenteriæ in an epidemic of dysentery in the Almshouse at New Haven, Conn. It now seemed likely that the bacteriologists were on the track of the cause of the summer diarrhœas of infants, and in the summer of 1902 at the Thomas Wilson Sanitarium, near Baltimore, Md., Duval and Bassett succeeded in growing bacilli from the stools of forty-two cases of "summer diarrhœa" in babies. No bacilli of this type were found in normal stools or in the stools of infants suffering from other diseases. Later, however, in the winter of 1902-1903, Strong, in Portland, claimed that he found the bacillus in normal stools during an epidemic of dysentery in young children. Park and Carey, Wollstein, and others have since confirmed the work of Duval and Bassett, and the most recent work done leaves no doubt that this organism, if not the sole factor in the etiology of "summer diarrhœa," at least plays a very important rôle in its causation.

Now that the cause of the disease has been discovered, there remains the discovery of the specific treatment along the same lines as that used to treat diphtheria. Unfortunately the constitution and powers of resistance in the infant are relatively so

weak, and the chances of secondary infection so numerous, that no one remedy however efficacious can be expected to be specific, especially when we consider that it is the gastrointestinal tract that is diseased, and the problem of feeding, which in a well child cannot be called simple, is made infinitely more difficult, so that the question of the infant's nutrition becomes, after all, the absorbing element. One may neutralize the toxins of the dysentery bacilli by the introduction of antidysenteric serum and yet have no control over a secondary streptococcus invasion, for example, nor can one by specific treatment help a marasmic infant to assimilate food.

A specific antidysenteric serum has been prepared and used successfully by Shiga in Japan. Gay, in this country, has also obtained a serum from horses immunized against B. dysenteriæ which is of considerable potency and which in relatively small amounts protects guinea-pigs against many times the minimum lethal dose of virulent bacilli. This serum was given an extensive trial during the past summer (1903).*

Whether it is eventually found that the serum treatment is specific or not, much can be done now in the way of prophylaxis in summer diarrhœa. Let us take up very briefly a few points that strike one most forcibly in the questions of treatment and prophylaxis. First of all there should be no segregation of babies in one large ward. Rooms should be of good size, well ventilated, and not more than three or four babies should be put in one room. One has only to go through a ward of ten or twenty infants to appreciate how jarring to the nervous system of the babies the constant crying must be. Segregation is fatal to babies suffering from intestinal disorders.

The importance of careful nursing cannot be overestimated. Infants should be occasionally taken from the cribs, their position in bed should be changed frequently, enough water should be given them to drink, and the bottle should not be stuck in the baby's mouth and left there to get cold. It is highly necessary to see that every child gets its full amount of nourishment and that it gets it warm. This entails a large force of attendants, but it is unquestionably the only right way to handle the sick children Hospitals where mothers are allowed to remain with their babies are to be recommended, for in such hospitals every child gets the individual attention that is necessary.

It is understood that rooms must be airy and easily cleaned and fumigated. Dysentery is a contagious disease, and should be treated as such. Special metal receptacles with covers are necessary for dirty napkins. These vessels should be frequently sterilized and all napkins should be boiled

It seems to the writer that not sufficient stress is laid on the ease with which infection can be carried from baby to baby in a ward. This may occur in one of several ways: (*a*) by the attendants, (*b*) by bottles, (*c*) by flies. It is not uncommon to see infants suffering from other than intestinal diseases develop diarrhœa when placed in a ward along with cases of summer diarrhœa. Hence it is important that such children be kept separately and have special attendants who do not handle the cases of diarrhœa. Attendants who have many children to take care of are not sufficiently careful in the disinfection of the hands after changing and bathing the infants. The chances of carrying infectious material from one baby to another is greater in proportion to the carelessness of the attendants.

*A full report will be published by the Rockefeller Institute for Medical Research.

The tendency of infants to put everything within reach in their mouths should be constantly in the minds of caretakers, and steps taken to keep the surroundings as clean as possible.

The bottle may come in for some of the blame. How often one sees the bottle picked up from the floor where it has fallen, a fresh nipple put on and given back to the baby. The bottle is also dirty; why not give it another bottle as well as another nipple?

Then there can be no doubt that flies carry the contagion. It has been shown that flies are capable of carrying virulent typhoid bacilli on their feet. If typhoid, why not dysentery? Both kinds of bacilli are in the stools, hence it can be reasonably inferred that both can be carried by the same means.

The rôle that drinking water plays as a means of carrying infection is of considerable interest. It has been noticed that infants in their own homes, fed on sterilized milk, develop summer complaint. It seems possible that in such cases infection may come from unboiled water used to dilute the milk (as suggested by Bassett), when the dilution is made and allowed to stand some time. One dysentery bacillus could in this way infect a large quantity of milk. The similarity to typhoid infection is great and would argue in favor of the transmission by water, although as yet no one has succeeded in cultivating the B. dysenteriæ from water. But when we realize how difficult it is to show the presence of B. typhosus in water and the much greater difficulty experienced in the ordinary cultivation of B. dysenteriæ from stools than of B. typhosus, we might take it for ganted that B. dysenteriæ can and does occur in water used for drinking. It is not claimed that infection cannot occur through undiluted milk, but when the milk is raised to the boiling point all bacteria other than the spore bearers and possibly the tubercle bacilli are killed. Raw, unsterilized milk may be and possibly is an important means of conveying the organisms into the gastrointestinal tract of children, but it should be borne in mind that water also might be a means of infection. The proper methods for obviating the chances of infection follow naturally from what has been said, and may be summed up in the words "careful nursing" and "wire screens or mosquito netting." Under the former would be included attendance, feeding, proper hygienic management, isolation of babies so far as possible, and careful supervision of the milk. No child should have unboiled water unless it is known to be pure, and the milk should be procured from a place known to be conducted in accordance with the modern dairy methods. With wire screens in the windows and doors, or mosquito netting over beds, the babies are well protected from their enemy, the fly.

Such, in brief, are some of the lessons taught by the discovery of the cause of summer diarrhœas. We were vainly groping more or less in darkness until the light of modern bacteriological methods was thrown on this problem, and to-day, with our better hygienic measures, our better milk supplies, our more intelligent corps of nurses and better trained doctors, not only the infant mortality, but also the infant illness, should be markedly decreased.

## HÆMOSPERMIA, WITH REPORT OF A CASE.

BY ARTHUR L. CHUTE, M.D.
BOSTON.

HÆMOSPERMIA, or the ejaculation of blood-stained seminal fluid, is an uncommon condition which is not in itself a disease, but a symptom occasionally seen in several diseases of the genito-urinary tract; it is probable, indeed, that it may rarely occur without any actual disease of these organs.

To most patients this symptom causes a degree of concern which is wholly out of proportion to its importance. Particularly is this true when it comes on, as it sometimes does, without apparent cause.

The following case, which I saw about a year ago, illustrates very well this particular type of hæmospermia. My reason for reporting a case which is so incomplete, from the standpoint of treatment, is the very small amount of literature, particularly in English, which I have been able to find on this subject.

The patient was a man of fifty years. His previous history was without bearing on his present condition, with the exception that twenty-five years ago he had a gonorrhœa complicated by a cystitis. Since his gonorrhœa, which did not run a protracted course, he has had no venereal disease, and has until the present trouble been apparently well.

For some weeks before he was seen he had noticed that his ejaculations had been of a reddish-brown color; they had not been attended with pain. He also had the feeling that there was a mass in his right inguinal region, though he could feel nothing. The patient had no diurnal frequency and did not have to get up at night to pass urine.

Examination showed no urethral discharge. His urine was perfectly clear; neutral in reaction. It contained no albumin, but did show a small amount of sugar. There was nothing to be felt in the right inguinal region where he had the feeling that there was a mass. His right epididymis contained a slight nodule which was suggestive of a former epididymitis; he, however, felt sure he never had epididymitis, and said the nodule followed an injury received in childhood. A catheter passed into his bladder without meeting any obstruction and showed no residual urine. There were no tender points in his urethra.

Rectal examination showed the prostate enlarged; it was rather difficult to reach the upper border; the right lobe was larger than the left; the gland was somewhat tender and boggy. After gentle massage of the prostate no material could be expressed from his urethra. No disease of the vesicles could be made out. The bladder was sounded for stone with negative results.

The only cause found for the hæmospermia was the chronic prostatitis. He was given hot rectal irrigations; a diet containing less sugar and starch than he had been taking; $\frac{1}{60}$ grain of strychnine three times a day.

At this examination I could get none of the reddish material, but some weeks later I received a piece of cloth which had been stained by a nocturnal emission. It was of a chocolate-color, and on soaking it in water I was able to find red blood corpuscles, but nothing else that I could distinguish. The examination was not at all satisfactory.

The patient lived some distance away and did not return for two months. At that time he said that his ejaculations were less deeply stained than they had been. His urine gave no sugar reaction, but in other respects his condition was as before. He was advised to continue the same treatment and to return for prostatic massage whenever possible. He, however, did not return and passed out of my knowledge until recently. In reply to a recent inquiry as to his condition he said that for a time last fall the trouble disappeared. It soon recurred, however, and his condition is now the same as when first seen.

In hæmospermia the color of the ejaculations is due to the mixture in varying proportions of blood and seminal fluid. This color ranges from red to chocolate; a rose tint has been noted; reddish-brown is, perhaps, the color most frequently reported.

Until recently it was supposed that the changes which took place in the extravasated blood accounted for the different colors; that the color was almost entirely dependent upon the length of time which elapsed between the hemorrhage and the ejaculation. It may be that in many instances this is so. Keersmaecker[1] has shown, however, that all the colors commonly seen can be produced by simply varying the amount of blood. He took the fluids gotten by massage from two cases of chronic prostatitis. One fluid contained a very large amount of blood, the other had none. By mixing these in different proportions the varying colors from rose to chocolate were produced.

Keersmaecker also cites a case by Gueillot in which a man had intercourse eleven times in one afternoon. Beginning with the eighth he had bloody ejaculations. The color varied from a rose tint at first to chocolate, and then to pure blood. This observation would also indicate that the color is not wholly dependent on the length of time which elapses between the pouring out of the blood and the ejaculation.

As stated before, quite a number of genito-urinary troubles have been known to act as the exciting cause of hæmospermia. The actual cause must always be, so far as we know, a lesion of the prostatic urethra, of the prostate, or of a seminal vesicle. I think no one has as yet reported any case in which the bleeding orginated in a vas deferens.

When the source of bleeding is a seminal vesicle, the mixing of the blood and seminal fluid takes place at once; this Feleki[2] terms "hæmospermia vera." When the bleeding is due to a chronic prostatitis or some lesion of the prostatic urethra the mixing takes place at the moment of ejaculation, and is what Feleki terms "hæmospermia spuria." It is said that in those instances in which the bleeding is from the posterior urethra or prostate, the ejaculation has a more streaked, spotted appearance, and that the mixture is of a less homogeneous color than when the source of bleeding is a vesicle.

I will cite briefly the opinions of several writers on this subject, and some of the conditions which they have found acting as the cause of hæmospermia.

Ultzmann[3] thought that the blood came, as a rule, from gonorrhœal lesions of the prostatic urethra, in the neighborhood of the caput gallinaginis. He says that in the fourth week of gonorrhœa one occasionally sees priapism with bloody ejaculations. He also says that hæmospermia may result from masturbation; that it is seen after sexual excess; in various diseases of the prostate and seminal vesicles, and likewise in malignant degeneration of the prostate.

Feleki speaks of the occurrence of hæmospermia

in diseased seminal vesicles.[4] He also gives an instance[5] in a boy of sixteen, in whom he attributed it to masturbation. Excessive coitus seems to have been the exciting cause in the case already referred to, as reported by Gueillot; also in one of three which Lichowetzer[6] has reported from Klemperer's practice.

Keersmaecker reports nine cases in which hæmospermia was due to chronic prostatitis. The report of his seventh case I think raises the question whether or not the bleeding may not have been due to a lesion of the prostatic urethra.

Finger[6] says that chronic prostatitis has a particular interest as being the cause of hæmospermia. He reports a case in which hæmospermia occurred in a patient with catarrhal prostatitis.

Lloyd[7] makes the statement that bloody ejaculations may take place in seminal vesiculitis.

Keersmaecker quotes Guyon as saying that hæmospermia is not infrequent in hypertrophy of the prostate.

Kroner[8] cites a unique case in which bloody ejaculations occurred in a man of forty-four, who, with the exception of an eczema, had been previously well. He had no syphilitic taint and did not come of a "bleeder" family. This patient some six months after the development of hæmospermia became "scorbutic," and died a little more than a year after his first bloody ejaculations. Kroner considered it a case of "sporadic scorbutus." The case was not reported in any detail.

While several writers refer to the occurrence of hæmospermia in cancer and hypertrophy of the prostate, I have not found detailed reports of such cases.

Keersmaecker, whose work on this subject is the most careful that I have found, believes that in nearly all instances the prostate is the source of the bleeding. He believes the cause of the bleeding is, in almost all cases, some type of chronic prostatitis. He feels that we must regard as exceptions to the rule the few carefully investigated cases in which chronic prostatitis has not been the cause.

Feleki, on the other hand, demonstrated with apparent certainty that in the case at least of his sixteen-year-old patient the source of the bleeding was a vesicle. He agrees that it is sometimes due to chronic prostatitis, but thinks that vesiculitis is a common cause.

In the two instances in which hæmospermia is supposed to have been due to congestion during excessive coitus, I feel that from the reports, at least, one cannot rule out the possibility of pre-existing disease of the vesicles or prostate. In these two instances, however, the condition did not recur, which decreases the probability of pre-existing disease.

From our present knowledge of this condition we may conclude that a transient hæmospermia may be due to excessive coitus, to a lesion of the prostatic urethra, and perhaps rarely to an acute seminal vesiculitis; that the persistent type is usually due to a chronic prostatitis, less frequently to a seminal vesiculitis; that rarely we may have hæmospermia due to cancer or hypertrophy of the prostate; that it has occurred in the hemorrhagic diathesis.

Most of the reported cases have been in young adults, the extremes of age have been sixteen and fifty.

In the great majority of instances the ejaculations have been painless. Keersmaecker quotes Kocher as saying that painful hæmospermia points to the lesion being in a vesicle. He does not, however, agree to this.

The [illegible] of the causal lesion in hæmospermio can usually be made by a careful examination of the patient. The presence of a lesion of the prostatic urethra, or the definite exclusion of such a lesion, can be made only by an endoscopic examination. The problem which presents the greatest difficulty is to determine whether the source of bleeding is in the prostate or a vesicle. The means most useful for this are those ordinarily employed to differentiate a chronic prostatitis from a seminal vesiculitis.

This procedure is as follows: The patient passes some urine to cleanse his urethra; the prostate is then carefully massaged; if possible, the fluid is massaged along the urethra and a specimen obtained from the meatus. If this last cannot be done the patient passes a second portion of urine, which contains the material expressed from the prostate. If the fluid gotten by either method is stained and shows, on microscopical examination, evidence of chronic prostatitis it is probable that the prostate is the source of the trouble. This is made positive if, after massaging the vesicles, we find they contain living spermatozoa, without blood or pus. If the conditions are reversed we may feel sure that the lesion is in the vesicles. If, after prostatic massage one finds spermatozoa in the material obtained, one has a mixture of prostatic and vesicle secretion, and the test is therefore not conclusive.

The prognosis in hæmospermia varies with the nature of the lesion on which it is dependent. As, in most instances, it is due to a chronic inflammatory lesion of either the posterior urethra, the prostate, or a seminal vesicle, the prospect for ultimate recovery is perfectly good. In those instances in which hæmospermia is due to malignant disease or hypertrophy of the prostate, the outlook is, of course, very different.

In a case of chronic prostatitis reported by Keersmaecker, bloody ejaculations which had existed for two years disappeared under massage and applications to the urethra. In the case which I have reported the condition has been present, with a short intermission, for a year, but this patient has had very little treatment, and is, therefore, not a fair example of what treatment can accomplish.

The treatment in this condition should be directed to the lesion on which the condition depends. If the lesion is in the prostatic urethra it should be treated by dilatation and applications of nitrate of silver, either by instillation or through an endoscope.

If the lesion is a chronic inflammatory condition of either the prostate or the vesicles, and the urethra is not involved, massage is the most important factor in bringing about resolution. This is oftentimes helped by hot rectal irrigations taken through a double-current tube. The massage should be repeated at intervals varying from a few days to a week. Where we have a lesion of the prostatic urethra as well as of the prostate or a vesicle, treatment must be directed to both lesions.

In the reported cases, treatment, when carried out faithfully, has given prompt and satisfactory results. Kroner's case, in which the hæmospermia was simply a sign of the hemorrhagic diathesis, is the only exception that I have found. It is improbable that hæmospermia in itself has any direct effect on the impregnating power of the seminal fluid. The lesions on which it depends may, however, be inimical to the vigor, or even the viability, of the spermatozoa.

---

**Solitary Tubercle of the Stomach.**—Roy McL. Van Wart reports this case. The patient was a negro woman, aged eighty-eight. When she entered the hospital she was much emaciated, unable to stand from extreme weakness, and refused to answer questions. In about five days physical signs of a bronchopneumonia became evident in the right lung, and she died two days later. At autopsy the stomach was found to be small, with the surface smooth except at a point 6 cm. from the cardiac orifice along the greater curvature where an area of thickening of the peritoneum was seen. Corresponding to this a tumor could be felt lying in the stomach and occupying the greater part of its lumen. The tumor was semifluctuant and was completely covered by the ribs. The external contour of the stomach was unaltered. The stomach was opened along middle of the anterior surface, and the tumor was then seen to lie entirely in the stomach wall and was covered by a perfectly intact mucosa, which bulged into the lumen of the organ at this point. The tumor was 3.5 cm. in diameter and almost spherical. On opening, it was found to contain a quantity of thick, yellow caseous material which flowed with difficulty. The wall of the tubercle was found to consist of necrotic material. The mucosa of the stomach was slightly infected and covered with mucus. The tubercle showed the following structure: The mucosa covering it was perfectly intact. There was no evidence of ulceration, or of an active inflammatory process, and it in every way resembled that from other parts of the same region of the stomach. The submucosa showed no change beyond a slight infection of the vessels similar to that seen elsewhere in the stomach. The muscularis was split in two layers, between which lay a layer of connective tissue passing gradually into a layer of cells which gave place to the caseous material of the tubercle. The cells in the second layer were of three types: Cells with large, deeply staining nuclei and little protoplasm, so called endothelioid cells, which in some places were arranged concentrically around a few scattered multinuclear giant cells. The presence of non-striped muscle completely surrounding the tubercle leaves no doubt as to the primary seat of the disease in the stomach. The question as to where the original focus of infection occurred is difficult to answer. Clinically the case is of little interest, as the condition gave rise to no symptoms during life. To conclude: The case is one of solitary tubercle in the muscularis of the stomach in which tubercle bacilli were found in the tissues and recovered from an experimental animal with the production of the typical lesions of tuberculosis. It is impossible to state whether the lesion was primary in the stomach, but there is no definite evidence to the contrary.—*Bulletin of the Johns Hopkins Hospital.*

**Autointoxication in Appendicitis.**—Edward Harnibrook holds that a toxic condition of the intestines is a frequent cause of appendicitis as well as a potent factor in causing the high mortality of the disease. His son, while studying comparative anatomy, dissected a putrefying dog, and had his first attack of appendicitis two days afterward. Medical students, hospital internes, and hospital nurses seem particularly liable to have appendicitis. The most trifling lesions are sometimes followed by death, while cases with suppuration, extensive adhesions, and gangrene often recover. Is not this because, in some cases, the toxins are not eliminated? The author believes in interval operations, for he holds that inflammation lessens the vitality of the part, and renders it vulnerable to subsequent attacks. For treatment of the infection causing the trouble, he gives ½ gr. doses of calomel every hour for two days, or until there are copious evacuations, and during the same period orders antiseptic enemata to be repeated every six hours, whether retained or not. He does not claim that antiseptic treatment will surely cure appendicitis, nor that it has any effect upon the localized inflammation, but he holds that it neutralizes the toxins in the intestinal canal, which are both a cause and concomitant of the disease, and that, therefore, it should be used both before and after the operation as well as when the case does not come to operation.—*The Canada Lancet.*

**Röntgen Ray Treatment of Cancer.**—William S. Newcomb reports a series of thirty-one cases of malignant disease treated by the *x*-rays. In this number are a few cases treated for such a brief period that no results could be looked for; but it was thought better to give a complete list rather than a selected one, and the only cases not reported are some of tuberculosis or of skin disease that could not be brought under the head of new growths. The conclusions based upon the whole series of cases are as follows: Small surface carcinomas (epitheliomas), if not too far advanced, will heal easily with the production of little or no scarring. When the disease has involved the deeper structures healing is less likely to occur, although a fair proportion will recover. Recurrences are very common, but if not allowed to advance too far will yield easily to treatment. Deep carcinomas and sarcomas will yield to treatment in a certain proportion of cases, but complications and metastases are to be expected. In nearly all pain will be relieved and surface ulceration healed, and this alone will prolong the lives of these victims and add to the comfort of themselves and of those about them.—*Therapeutic Gazette.*

**Lipæmia in Diabetes Mellitus.**—Thomas R. Fraser reports a case of diabetic coma in which a remarkable production of fat in the blood was not only demonstrated at the post-mortem examination, but had also been determined during the life of the patient. From a study of the subject he states that there is strong evidence in favor of the view that in diabetes the sugar in the blood may, by causes which are not known, and by processes which cannot at present be explained, abruptly undergoes more rapid and more abundant chemical transformations than were previously occurring, with a result, in a considerable number of cases, of a sufficient acidosis to produce the peculiar intoxication which is distinguished as acetonæmia, and in a small number of cases, of the formation also of a large quantity of fat in the blood, constituting the condition of diabetic lipæmia. It is not improbable that in accordance with the amount of this fat in the blood the solvent capacity of the serum for oxygen would become reduced, and that thereby the death-producing power of the existing acidosis would be reinforced. The author urges that in patients suffering from diabetes the urine and blood should be examined at intervals of one or two weeks for B-oxybutyric acid and fat respectively, so that the earliest warnings of danger may be obtained, and the earliest opportunity afforded for treatment by a liberal administration of alkalies.—*The Scottish Medical and Surgical Journal.*

**A Granuloma of the Nose, Due to Iodide of Potassium.**—C. Percival Crouch reports the case of a man who was put on antisyphilitic treatment for disease of the nose and larynx. After a few weeks some spots appeared on his forehead like an iodide rash, and a small raised granuloma appeared on the tip of his nose and rapidly increased in size, while similar growths presented themselves on forehead and temples. It was decided that the growth was due to the action of potassium iodide on a syphilitic subject, to a great extent increased by an existing heart lesion, which prevented the proper elimination of the iodide. Iodide was discontinued, arsenic was given, and caustic

applied. The growth has not returned. Acne due to iodine is apt to become tuberous. Iodide rashes are more apt to occur if there is either cardiac or renal disease present. An iodide rash may begin within twenty-four hours after the exhibition of 5 grains of potassium iodide three times a day.—*The British Medico-Chirurgical Journal.*

**The Treatment of Cancer, Lupus, and Other Malignant Growths with Concentrated Sun's Rays.**—O. U. Thayer, more than thirty years ago, commenced this form of treatment on diseases of the skin and its appendages. He has operated more than two thousand times with the concentrated sun's rays and has never noticed any permanent injury from them. No other remedy can compare with it as a curative power. Unlike other caustics and cauteries, it can be applied with perfect success to the most delicate membrane or tissue; the general system receives it kindly, the irritation and inflammation following its application are surprisingly slight and of short duration. The pain subsides immediately upon removal of the lens. Blistering is avoided, as the tissues are carbonized. The morbid tissues, having less vitality than the normal or natural structures, succumb to the solar heat before the healthy tissues adjoining are injured. In the treatment of cancer and lupus, the remedy is at once safe and certain. Many less treatments are required than with the Röntgen rays, the cure is more certain, the wound remaining heals sooner, and the skin is restored in great measure to its normal condition.—*Pacific Medical Journal.*

**The Serum Precipitation Test for the Identification of Blood Stains.**—J. W. Mallet gave a chicken five injections, at intervals of a few days, of blood taken from negroes, and it was then killed by bleeding. The antiserum of this chicken's blood was then tested at various degrees of dilution, with samples of negro and Caucasian blood, also variously diluted, the samples being treated side by side. and precisely alike. In both cases a precipitate was formed, but there was a clearly perceptible difference: that derived from the negro blood was distinctly more marked in amount, and in the weaker dilutions formed more promptly than that in the sample of blood from a white man. Upon so slender a basis as this experiment, it would be rash to assume that a general conclusion of trustworthy character has been reached. But, as far as one experiment goes, it is interesting, and seems to render probable the future availability of the reaction for identification of the race source of a human blood stain.—*Virginia Medical Semi-Monthly.*

**Syphilis Considered in Its Ethical Relations.**—S. Seabury Jones says that, according to authorities who have investigated the subject and studied the question of a remedy, it is admitted that from 50 to 85 per cent. of cases of syphilis among females have been innocently acquired. This showing would suffice to justify us in any measures, not oppressive, which may tend to protect the innocent against the ravages of this disease. Much responsibility rests with the physician. It is extremely difficult to know how to protect a wife and children against contagion, without wrecking her happiness, but a husband can, perhaps confess the nature of the malady, concealing the nature of its acquirement. No physician is justified in treating a young unmarried man for syphilis or gonorrhœa without confiding to the father the nature of the disease and the measure necessary to protect the family from contagion.—*Medical Review of Reviews.*

**The Hygiene and Dietetic Treatment of Chronic Nephritis.**—Victor C. Vaughan states that recent investigations have shown that there is good reason for concluding that in certain forms of chronic nephritis, nephrolysins are found in the circulating blood of the patient. These nephrolysins are albuminous bodies, and when injected into the blood of experimental animals lead to degenerative changes in the renal structure, and to death. If this be the case, then the hygienic and dietetic treatment of chronic nephritis should be directed toward the possibility of profoundly altering the proteid constituents of the blood. The author has found a diet wholly vegetable, with the exception of cream and butter, to be the most serviceable. Meat in any form, eggs and milk are forbidden. Corn meal mush is the best cereal, with sugar *ad libitum* for the mush zwieback, butter, potatoes, legumins, green vegetables, fruits, and melons are allowed. The digestive organs need to be watched closely, and the bowels must be kept in good condition, but copious purgation is not desirable except during exacerbations or for the removal of dropsical accumulations, or in threatened uræmia. The skin should be kept in a normal, but not too active state—a hot bath three times a week and a Turkish bath once a month, as a usual thing. Flannel underclothing, medium to heavy in winter and light in summer, is prescribed.—*Northwest Medicine.*

**The Inter-relations of Diabetes and Other Constitutional States.**—George F. Butler says that it is a great error to fix upon glycosuria as the one test of diabetes, since it may occur in so many other conditions, such as various neroses, delirium tremens, febrile conditions, pregnancy, gout and insanity of the autotoxic types, etc. The author gives the various symptoms of diabetes which may tend to confound it with other diseases such as locomotor ataxia, epilepsy, etc. Clinical study demonstrates beyond doubt that most cases of diabetes are at first expressions of nutritional and assimilational instability. In consequence of the overstrain on the liver, adrenals, pancreas, spleen, and kidneys, what were at first merely biochemic changes in these organs become permanent pathological lesions, continuing constantly in excessive sugar manufacture without proper oxidation or elimination.—*The Canada Lancet.*

**Eyestrain and Functional Disorders.**—Charles A. Wishart holds that eyestrain bears a causal relationship to functional disorders of the brain and viscera. The so-called idiopathic epilepsy may have its starting point in ocular strain; Dodd reports forty-nine cases which were cured or benefited by the relief of the eyestrain. Chorea is also due to the same cause in some cases. The ill effects of this trouble are not confined to the nervous system; all of the visceral functions may be disturbed, as all the viscera depend on the brain. The author reports the cases of dysmenorrhœa relieved by correction of muscular error of the eyes. A claim that all functional derangement is the result of eyestrain would be absurd, but the claim that many derangements of functions of various organs is the result of reflex nervous irritation is easily susceptible of proof, and that eyestrain is one of the commonest causes of such reflex irritation can be demonstrated with almost absolute certainty.—*Pennsylvania Medical Journal.*

**Is the Urban Hospital Treatment of External or Surgical Tuberculosis Justifiable?**—A. H. Tubby draws the following conclusions from his investigations of cases treated in towns and in the country: The number of cures is by no means so great in towns, nor is the cure as complete; the number of relapses being far greater, as is shown by patients continually going the rounds of the hospitals. Operations are more frequently resorted to in the city, and are by no means always successful. Better results are obtained in those cases which are treated by rest from the first and when there is no excision or ablation of bone and wide cutting of soft parts. Tuberculous children should be placed in properly equipped establishments in the country or at the seaside. These hospitals should be devoted to one object only, just in the same way as sanatoria exist for the open-air treatment of phthisis alone. There should be no limits as to age, younger children being as eligible as older ones. Cases once admitted should stay until cured, or clearly proved to be incurable, and for the latter separate establishments should be provided, so that they cease to be a danger to the community.—*The Practitioner.*

## THE TRANSMISSION OF BOVINE TUBERCULOSIS BY MILK.

DR. GEORGE M. KOBER, in the *Journal of Medical Sciences*, October, brings forward a mass of evidence in support of the view that tuberculosis can be caused in human beings by means of the ingestion of milk from diseased cows. Carmichael, in his "Essay on the Nature of Scrofula, with Evidence of Its Origin from Disorders of the Digestive Organs, London, 1810," referred to the part played by milk in the causation of scrofula. This writer quoted yet more ancient authors, Richard Wiseman (1626–1686), White (1787), and Leutand, to show that whenever the outward glands appear swollen, one may safely conclude the mesenteric to be so, too, they being usually the first parts to be attacked by scrofula.

Casper, in his "Characteristics of French Medicine, 1822," suggested the connection between the fact that the majority of milch cows in Paris were affected with nodular consumption, and the prevalence of scrofula among the young children of that city. Hencke, in 1846, was the first to advance the theory that scrofula was caused by the milk of infected cows. During the past two years experiments made by Ravenel de Schweinitz, Mohler Orth, de Jong, Stenstrom, Fibiger, Wollff, Nocard, Arlong, v. Behring, Dean and Todd "conclusively demonstrate," says Dr. Kober, "that cattle are not refractory to human tuberculosis, and that bovine tuberculosis may be transmitted to monkeys. The author has tabulated eighty-six cases of milk bovine tuberculosis, and states that "the statistical work of Gottstein shows that the mortality from tuberculosis in breast-fed children is but slightly more than half as much as among those otherwise nourished, the proportion being as 6:10."

Salmon has analyzed the vital statistics of Massachusetts and finds an increase of 36 per cent. in the forms of tuberculosis other than phthisis in the cases under five years of age, while there was a reduction in the mortality of phthisis at all other ages of about 45 per cent., and the vital statistics of Michigan from 1885 to 1900 show also an immense increase during the milk-drinking age.

Dr. Kober makes the following suggestion: "The opportunities for tracing bovine infection are much better in small communities and in isolated farm-houses than in large cities, and we should look to the country practitioner for help; he, in turn, unless properly equipped to verify the diagnosis, should apply to the Bureau of Animal Industry, or to the pathologist and bacteriologist of his medical school to check up his work."

The writer draws these conclusions: (1) Tuberculosis may be transmitted to man in milk from tuberculous cows. The danger from this source is real and cannot be measured by the actual number of recorded cases, but should be judged, in part at least, by the inoculation and feeding experiments, and the accidental wound infections which have established the intercommunicability of bovine and human tuberculosis. (2) The degree of danger may also be estimated by the prevalence of bovine tuberculosis and of forms other than phthisis pulmonalis in man, remembering that the infectious qualities of milk are greatest when the udder is the seat of lesions and that Gebhardt's experiments have shown that tuberculous milk when diluted with the milk of sound animals in the proportion of 1:40 lost its power. (3) The experimental studies also indicate that while the bacilli of human tuberculosis possess different degrees of pathogenic power and are often of feeble virulence for cattle, Koch's assumption that human and bovine tuberculosis are distinct and that human tuberculosis cannot be conveyed to cattle appears to be disproved, and his failure to secure similar results may be attributed to the use of human bacilli of diminished virulence. (4) Recent investigations have strengthened Smith's claim that there are two types of tubercle bacilli—the so-called bovine and human types—possessing certain morphological and biological differences; but it has also been shown that virulent cultures may be obtained from both of these types, which, when inoculated into animals, produce the disease in question. (5) Further research seems desirable with a view of determining the frequency of primary intestinal and abdominal tuberculosis in all cases which come to autopsy, whether the child perished from tuberculosis or not, and in these autopsies the bacteriological examination should be directed to the existence of the two types of tubercle bacilli originally referred to by Smith, and whether the bovine type predominates in the so-called scrofulous lesions. (6) Careful chemical analyses of the milk of tuberculous animals should be made with a view of determining the amount of phosphoric acid as compared with the quantity in normal milk, since it appears probable from Dr. de Schweinitz's biochemical researches that the excess noticed by the older chemists is really the result of bacterial activity in the udder of the cow. (7) In the meantime the pathologist has no reason to reverse his opinion as to the identity of human and bovine tuberculosis, and the sanitarian has no reason to assume that the human subject is immune against infection with the bovine bacillus, or is so slightly susceptible as to cause him to relax his efforts in preventive measures.

It would seem that the majority of scientific men are veering toward the belief that bovine tuberculosis can be transmitted to human beings, under certain circumstances.

The numerous experiments undertaken since the promulgation of Koch's views support—to a greater or less extent—this attitude. The sooner that the question is definitely settled the better it will be for the public at large, and for this reason it might be well that the advice given by Dr. Kober

should be closely followed. Pending this event, no precaution should be relaxed in the way of keeping the milk supply pure. A strict supervision of this necessary commodity is just as strongly indicated as it ever was.

## HOW IS CARDIAC DROPSY PRODUCED?

CONCERNING the method by which dropsy is brought about, there are three theories: (1) the secretory, that the cells of the capillaries have a specific secretory function, an abnormal increase of which (as a result of stimulation by the excess of waste products in the blood) results in dropsy; (2) a theory that a malnutrition of the tissues and accumulation of waste products are the most important factors, the blood vessels playing a minor part; and (3), the mechanico-physical theory, that dropsy must result when the lymph circulation is hindered both by a diminished *vis a tergo* (the outcome of diminished arterial pressure), and by an obstructed outflow into the veins, the results of increased venous pressure.

In the *Journal of Pathology and Bacteriology* for August, Dr. Charles Bolton examines the respective merits of these theories. The first question is: What, as a matter of fact, is the state of the arterial and venous pressures. The method employed consisted in the interposition of a mechanical obstruction to the heart's action, by constricting the pericardium by sutures.

As a result, the emptying of the veins into the heart is hindered. The experiments were all upon cats. Three groups of experiments were made, namely: those in which the animals were allowed to recover to see whether dropsy would result; those in which after the constriction was made and the arterial and venous pressures were noted, the animals were killed; and those in which the subsequent changes in arterial and venous pressures, while dropsy was being produced, were noted. In the first group the classical picture of uncompensated disease (with dyspnœa, diminished amount of urine and dropsy) was produced. Whether albuminuria resulted could not be decided with absolute certainty, as etherization sometimes results in a trace of albumin in the urine. The dropsy was much more frequently limited to the serous cavities, which shows that when the effect of gravity does not come in as a disturbing factor, the dropsy of heart disease first appears in these cavities.

The studies of the blood-pressures showed the arterial pressure everywhere diminished and the venous pressure everywhere (in the peripheral and portal veins, as well as in the large vessels of the trunk) increased. By increasing the volume of the blood (by the production of hydræmic plethora) it was impossible to restore the arterial pressure to normal. When, therefore, the heart fails to maintain the normal output, there results primarily diminished arterial and increased venous pressure. The latter, however, eventually passes off (probably owing to a yielding of the walls of the veins), and the venous pressure returns to normal. But when this return of the venous pressure to normal has taken place the arterial pressure is still below normal, and continues below normal while œdema is taking place. So that during the formation of the œdema the pressure in the capillary system is, as a matter of fact, below normal. The existence of this lowered pressure in the capillaries, and the simultaneous slowing of the circulation through them, renders it, the author thinks, much more probable that the production of dropsy is attributable primarily rather to impairment or other alteration in the function of the capillary wall, than that it is due to heightened function in the same.

## POISONED WOUNDS BY THE IMPLEMENTS OF WARFARE.

FROM an editorial review in the *Journal of the Association of Military Surgeons*, of a lecture by Major L. A. LaGarde, Surgeon, U. S. A., we abstract the following, both on account of it, practical as well as medicolegal importance. The literature of poisoned wounds gives ample evidence that the poisoning of projectiles has been practised from prehistoric times to the present day. It is also evident that not only vegetable but also bacterial poisons have been employed. The introduction of firearms about the fourteenth century, however, threw much doubt on the possibility of continuing the practice of the ancients. LaGarde's observations show now that the explosive and the ball are contaminated in 12 and 47 per cent., respectively, of the specimens examined, and also that they become contaminated by handling. The wad and wadding are always contaminated. Moreover, the heat generated during firing does not destroy bacteria existing in the powder, or the wad, or on the ball or the barrel of the gun, and bacteria placed anywhere in black or smokeless powder, or in the barrel, can invariably be recovered from media into which the missile is discharged. Thus it has been demonstrated for bacillus anthracis, when placed either on the bullet or in the powder (smokeless or black). Also the experiments proved that tetanus can be conveyed into an animal when the bacillus is placed anywhere from the powder to the point of impact on the skin.

An infected wound, however, need not necessarily come from an infected missile, as the latter may become infected *en route*, as from penetrating infected clothing. The character of the lesion, so far as it relates to the local resistance, is of prime importance. Hæmatomata in particular involve a special predisposition to infection, and as gunshot wounds often partake of the nature of a hæmatoma (in addition to lacerations and other injuries leading to necrosis), such wounds must be regarded as at least as liable to infection as hæmatomata; and Strick's experiments show them to be even more so.

Concerning vegetable poisons, such as curare and ricin, there is nothing in the act of firing to destroy their lethal properties, and they are readily conveyed when placed on the ball or barrel, or in the powder, and undoubtedly toxins and animal poisons, such as snake venom, could be conveyed in the same manner. With vegetable poisons the experiments showed that clean incised wounds absorbed the poison more rapidly than other wounds, and that death was more rapid. Respecting poisoned wounds as they actually occur to-day, taking tetanus as an example, its occurrence is very frequent both in civil and military life, as a result even of toy-pistol and blank-cartridge wounds. LaGarde also points out the medicolegal aspects of

the subject and the possibility of intentional infections of projectiles. In suspected criminal attempts the surgeon should make a thorough examination of the ammunition and weapon, including a chemical and bacteriological examination of the powder, bullet and barrel; powder grains found in the clothing or wound should be carefully collected; the projectile when recovered should be dropped into media, with sterile forceps; the inside of the barrel should be examined for specific microorganisms; and a thorough study made of all of the ammunition remaining in the weapon. If the shot was a ricochet, the initial point of impact should also be examined for the presence of poison. The same measures should be taken in the examinations for toxins and animal and vegetable poisons. Concerning the method of identification in these cases, Welsh says: "The only certain means of detecting toxins of the class of diphtheria or tetanus toxin, snake venom, and certain vegetable poisons of the same category, is their neutralization by the corresponding antitoxic sera. Occasion may arise when such detection is of practical and even medicolegal importance, as has been exemplified in India, where the criminal use of cobra venom is not unknown." When the evidence of poisoning has been shown, the prosecution should endeavor to establish the poison found: (1) On the instruments; (2) the dressings; (3) the hands of the attendants; (4) the clothing, and (5) the skin of the patient. This part of the evidence can be readily gathered if the surgeon in charge is on the alert and acts at once. In all the examinations for bacteria special attention should be paid to the identification of strict anaërobes by animal experimentation as well as by culture methods.

---

### The Prevention of Tuberculosis.

The International Congress of Hygiene and Demography has recently held a meeting, and, naturally, one of the subjects most earnestly discussed was that of the most effective means of fighting tuberculosis. The opinions of the many eminent physicians present did not agree on all points relating to preventive measures. For instance, with regard to the good wrought by notification, the views expressed diverged considerably. Dr. Brouardel of France was not altogether in favor of the system. Dr. Moeller said nothing in praise, or dispraise, of notification, but was non-committal. Professor Pannwitz of Germany "was of the opinion that there ought to be obligatory declaration of change of abode by those having infectious discharges."

Dr. Newsholme of England described the success of the introduction of notification into many English towns, and was the most enthusiastic eulogist of what may be termed the American method.

The relation between alcoholism and tuberculosis was another matter which received much attention at the hands of those who attended the Congress. Dr. Brouardel recapitulated his well-known opinion, that alcoholism is, perhaps, the most fruitful cause of consumption, and Professor Landouzy concurred in these views.

The influence of social comfort and food upon the causation and prevalence of tuberculosis was also dealt with at some length. The belief is widespread —indeed universal—that good living, decent houses, and good sanitary conditions generally, will do more to check the dissemination of tuberculosis than any other means. At the Congress statistics were brought forward in support of these points. Attention was drawn by the English delegate to Sir Hugh Beevor's Hunterian oration in which he showed that the curves of price of wheat and mortality from phthisis followed each other almost exactly, but as Dr. Newsholme aptly pointed out, the price of bread is only one factor in the case, improved conditions of life must be considered as bearing upon the matter with equal weight. The members of the Congress, with scarcely an exception, were agreed that in order to wage a winning fight against consumption, special hospitals and sanatoriums for its treatment must be established. Isolation for the advanced cases, and sanatorium treatment in the country for incipient cases. Without these means a campaign against tuberculosis must of necessity come to nought.

### Faith Healing in Great Britain.

It would appear from the account of recent happenings in Great Britain, that Christian Scientists, Faith healers, and others of a like ilk are gaining a foothold there. Until recently but little has been heard of fanaticism of that kind in the United Kingdom, and the United States has been regarded as preëminently the happy hunting ground of those who had stepped out of the beaten path, either as regards religion or medicine.

That Dowie has his followers on the other side has been proved, however, by a case which was reported by the Manchester correspondent of the *Lancet*, October 10. A man was charged in that city with wilfully neglecting and ill-treating his young daughter, and was tried on October 1. The child, on September 3, fell down some steps and broke her right collar bone. On returning home the father was told of the accident, and although the mother wished to send for a medical man, he would not allow it, and based his faith upon the curative efficacy of earnest prayer. On September 11 the Society for the Prevention of Cruelty to Children intervened, but it was not until September 21 that, by an order of the Court, an inspector of the society took the child and she was properly attended to. The defendant at his trial testified that one of the principles of his church was that "all cures were effected by means of faith and prayer." He is also said to have send a cablegram to "Dr. Dowie" at Zion City asking for his prayers, but had no reply. The man was sent to jail for a month with hard labor.

The progress of Christian Science, of Faith Cure, and of other quasi-religions is one of the most interesting features of the present time, and affords the student of human nature ample study. Whether to regard Mrs. Eddy or Dowie as fanatics is a moot-point. Probably, taking into consideration their methods, most people will be of the opinion that these are not disinterested, and that they are swayed by mercenary motives and vanity. Whatever, however, may be the guiding principles of the leaders, there can be little doubt but that the great majority of their followers are sincere in their beliefs, and are ready and eager to offer themselves as martyrs to their religious convictions. They are sheep to be shorn by their too astute shepherds. Be this as it may, the children of such people must not be allowed to suffer for the eccentricities of their parents. An adult has a right to go his own way—within certain bounds—but he has no right to insist that his child or charge should pursue the same course if it be to his or her physical detriment. Therefore the decision at Manchester should commend itself as wise to every reasonable person.

### The Causes of Physical Degeneracy.

At the recent meeting of the British Medical Association, Professor Herbert H. Tidswell Chester read a paper on this subject, which is now greatly exercising men's minds, particularly in Great Britain. Dr. Chester holds that overtaxing the mental capabilities of the children of the poor is the main reason for their deterioration in physique and stamina. He thinks that the children of the working classes nowadays commence school attendance too young, He says: "Children's brains are delicate organs and require gentler treatment than they often receive at the hands of their teachers. The cram system of the present day is both demoralizing and degrading, and is calculated to render the judgment unstable and capricious and to interfere seriously with the mental equilibrium. The development of the body is seriously retarded by a morbid condition of the cerebrospinal system. Dr. Chester makes the following suggestions as to remedying the existing condition of things: (1) If possible, remove the cause of mental strain and abolish the cram system. (2) Let all schools be under systematic medical inspection; let a medical officer be attached to each school, who shall inspect each class as it assembles, to detect infectious or other diseases in the early stages, who shall examine the eyesight, the hearing, and general condition of each child and keep a report of the same, who shall visit any pupil at home in case of sudden illness and give certificate to same.

Dr. Dawson Williams, editor of *British Medical Journal*, who took part in the discussion, concluded that the practical question appeared to be, whether the factors which tended to prevent adequate physical development could be removed. As he understood the matter, it was the defects in the diet of infancy and youth causing a condition of defective nutrition which produced not only imperfect physical development, but imperfect or retarded cerebral development, which was the cause of what was called overpressure.

---

### Plague in Domestic Animals.

Among the papers read at the Tropical Section of the British Medical Association, the meeting of which was recently held, was a short but pertinent one on the above subject by Mr. James Cantlie. It appears a report was sent from Hongkong that several fowls, a duck, and a quail exposed for sale in the market of that city were found to be infected with plague. That domestic animals and birds may become infected with certain diseases, which they may transmit to man, has been suggested on several occasions, and has been stated as a positive fact more than once. However, little notice has been taken of these views, and for the most part they have been politely poohpoohed as visionary. Mr. Cantlie points out that the experiments undertaken by Prof. W. R. Simpson and Dr. Hunter in Hongkong cast more light upon the matter, and teach us new facts in connection with the infectivity of domestic animals. By vaccinating, inoculating, and more especially by feeding animals on plague cultures, or on the blood or organs of plague-infected animals, Professor Simpson showed that monkeys, sheep, calves, pigs, fowls, geese, ducks, pigeons, turkeys, etc., readily contracted plague, and one of the most telling results of his observations has brought home to us the fact that they more readily became infected when fed upon plague bacilli in any environment than by any other known means of causing infection. He proved, also, that the bacilli were found in the flesh, in the organs, and in the excretions of these animals, and the fact that skin parasites readily acquired the bacillus when fed on plague-infected animals has been long known to us. In China and Oriental countries domestic animals often live under the same roof with the family, so that whether animal or man contract the plague it is certain to spread, and if transmissible from animal to man, as seems probable, the disease will be disseminated among human beings. According to Mr. Cantlie, it has been, to a large extent, proved that a very large number of animals and birds of all kinds can become infected with plague. What is wanted, in his opinion, is a ready means of diagnosing plague in animals, "for," as he says, "to take the temperature of each pig of a large consignment, or to examine the blood for plague bacilli, is an ordeal the best equipped port officers could not go through. Could we tell by inspection that an animal had plague, we might hope to be able to control the disease in some measure, but until we discover a rapid means of diagnosing plague in animals, there is little hope of combating the spread of the malady."

---

### Nursing as an Occupation.

An annotation which appeared in the *British Medical Journal*, August 8, on this subject has aroused much attention, and has led to a considerable amount of correspondence. The question of the status of the trained nurse, and the loose definitions of the qualifications which give a person the right to lay claim to that appellation, have been referred to several times in the Medical Record. It would appear that in some respects the situation as regards nurses is quite as unsatisfactory in England as in this country. The market there is overstocked, and individuals with little or no training are allowed to compete on equal terms with those who have gained skill and experience from three years of hospital work. The aforementioned annotation in the *British Medical Journal* contains a plaint from a physician with regard to the incompetence and ignorance of many of the self-styled nurses, and gives an instance of the lengths to which such lack of knowledge, joined with impudent assurance, can go. The correspondence called forth by this communication has been interesting and at the same time timely.

One writer declares that if medical men are content to trust their patients to any woman posing as a "nurse" without inquiring as to her qualifications for the work she undertakes, they must bear at least some of the blame for the resulting danger to the public.

The gist of the argument of all the writers is that the State should initiate a system of registration for nurses. One correspondent says, "Surely it is time that the minimum standard of nursing should be defined by authority, and that those who are endorsed by their training schools, and who have given proof that they have attained this standard should be enrolled in a register under the authority of the State." It is pointed out that registration of nurses is already in force in Cape Colony, Natal, New Zealand, and in four of the States of this country. Another correspondent draws attention to a saying of the late Sir James Paget. "In the same family one sister takes a medical qualification and is registered, another becomes a nurse and she cannot be registered. The contrast is becoming ridiculous as well as unjust, and must soon come to an end."

A medical man writes as follows: "We as medical men should do all in our power to help the nursing profession out of its chaotic state, and to put it on a firm and practical footing, because the two pro-

fessions have so much in common; secondly, we shall be doing a greater duty to our patients if we try all we can to prevent their being left in the hands of experienced persons posing as so-called 'trained nurses.'"

Finally it is stated that a bill is now being drafted in Great Britain by the Society for the State Registration of Trained Nurses, the object of which is to ensure that nurses are really trained.

The present condition of affairs is anomalous and unpractical as well as decidedly unfair to the well-trained nurses and the public at large. If the public could be made to realize the importance of having the services when sick of a thoroughly trained nurse, the question of registering nurses would not be long left in abeyance. Good nursing is a most essential factor in the treatment of disease, and for the sake of all concerned it is expedient that registration of nurses should be introduced as speedily as possible.

### Late Marriages and Cancer.

At frequent intervals within the past few years, announcements and surmises have been made as to the cause of cancer. Some of these have had a scientific basis, while others have appeared to be the result of a vivid imagination. They, however, all go to show the intense interest which is manifested in the subject, and tend to raise the hope that the time may not be far distant when the mystery of the origin of this dread disease will be solved. In the meantime the accounts of the various suggested causes will be read with attention, not, perhaps, unmixed with a certain degree of amusement.

In the July number of the *London Polyclinic*, of which Mr. Jonathan Hutchinson is editor, appeared a leading article, bringing forward the hypothesis that late marriages may have an important influence upon the causation of cancer. The article commences with the perfectly fair assumption that the offspring of middle-aged or elderly parents are not born with precisely the same proclivities and endowments as those of the young. After discussing the question of the transmission of physical and mental traits from parents to children, and through several generations, the writer proceeds to consider the subject in debate. He asks, if the later born children of a gouty parent inherit any greater liability to gout than the first born? and answers thus: "It is scarcely likely that a child born after his father has lived fifty or sixty years, and passed through many attacks of gout, will be in precisely the same condition as one born in his parent's youth. It is surely reasonable to believe—*pace* Weissmann—that he will in some way inherit the tissue proclivities which his parents had acquired." Taking it as more or less proved that the child of an elderly, gouty man will inherit a predisposition to the same disease, the theme is continued as follows: "If we now pass from gout to cancer it may be suggested as a primary proposition that the nearer to the cancer-period in the parent the child is begot, the greater is the risk that he may inherit a tissue proclivity to the cancerous process. Now the cancer period is that of middle age and commencing senility, emphatically it is not that of youth. The children born to young parents are begotten with very rare exceptions at periods long prior to the development of cancer, or of any special tendency to it." The assertion is made that the hypothesis is in accordance with facts. It is pointed out that cancer is far less common in the lower animals than in man, and they, as a rule, wed early, while in man the disease is far less frequent in lowly-civilized communities than it is amongst the superior nations of the world. The increase, in fact, has occurred almost solely amongst the people of the highest civilization, and with whom the marriage age has been steadily increasing for centuries. Of course many seemingly destructive arguments can be brought against the supposition as to the cause of cancer advanced in the Polyclinic, but, on the other hand, it has several points in its favor, and it is at least as plausible as several of the theories which have been thrust in our faces during the last two or three years.

## News of the Week.

**Dr. Bulkley's Lectures on Skin Diseases.**—Announcement is made of the sixth annual course of clinical lectures on diseases of the skin to be given by Dr. L. Duncan Bulkley, in the out-patient hall of the New York Skin and Cancer Hospital, Second Avenue and Nineteenth Street. The lectures will be given every Wednesday afternoon at 4.15 o'clock, beginning Wednesday, November 4. These courses are free to medical practitioners, and are always largely attended by out-of-town physicians here for post-graduate study as well as by residents of the city.

**Officers of the Public Health Association.**—The American Public Health Association, which was in session last week in Washington, elected the following officers to serve for the ensuing year: *President*, Dr. Carlos J. Finlay of Havana, Cuba; *First Vice-President*, Dr. J. R. Monjaras of Mexico City; *Second Vice-President*, Dr. William C. Woodward, health officer of the District of Columbia; *Secretary*, Dr. Charles O. Probst of Columbus, Ohio; *Treasurer*, Dr. Frank W. Wright of New Haven, Conn.; *Executive Committee*, Dr. A. H. Doty, health officer of the port of New York; Prof. F. C. Robinson of Bowdoin College, and Dr. John L. Leal of Paterson, N. J. It was decided to hold the next meeting in Havana.

**New Lebanon Hospital Ward Opened.**—A convalescent ward of one hundred beds was opened in the Lebanon Hospital, Westchester Avenue and One Hundred and Fiftieth Street, in The Bronx, on November 6. Admission to the convalescent wards will be from the other wards of the hospital and through the United Hebrew Charities, which will investigate and make recommendations upon all charity cases.

**The New York State Association of Railway Surgeons.**—The thirteenth annual meeting of this society will be held at the New York Academy of Medicine on Thursday and Friday, November 12 and 13, 1903, under the presidency of Dr. Henry Flood of Elmira. The Secretary is Dr. George Chaffee of Brooklyn. On Thursday, at one o'clock, there will be a luncheon in the grill-room of the academy, and on Friday clinics will be held by Dr. Joseph A. Blake at Roosevelt Hospital, at 10 A.M., and by Dr. Frederick H. Wiggin at City Hospital, Blackwell's Island, at 2.30 P.M.

**A Quarantine against Allegheny.**—The Pennsylvania State Board of Health has declared a limited quarantine against Allegheny because of the continuance of smallpox which has existed in the city for several months. The quarantine will be confined to the fumigation of outgoing mails, prohibition of the transfer of baggage from one portion of the city to another and the publication in the papers of western Pennsylvania of a formal notice from the State Board, calling attention to the danger of holding communication with Allegheny or receiving persons who have come from there.

**Poisoning of Asylum Inmates.**—The attendants at the Tewksbury, Mass., State Hospital dis-

covered at the breakfast hour the other day that eleven of the inmates had developed symptoms of belladonna poisoning. Prompt measures were taken to relieve the sufferers, and some of the men were soon out of danger, but one died. An investigation is being made by the State Board of Charities.

**The Yellow Fever** situation in Texas is improving. Cases continue to be reported from Laredo and a few from San Antonio, and the quarantine against these places is maintained despite the protests of their citizens. The quarantine against San Antonio has been absolute, the Governor of the State having issued an order mandatory upon all railroads not to operate trains in or out of San Antonio or to handle any freight or passenger business from that city in any shape whatsoever. The Louisiana Board of Health has quarantined against Laredo and San Antonio, and all railroads and other common carriers are prohibited under penalty from bringing into Louisiana passengers, household goods, and cars from those places unless they are first fumigated with sulphur by authorized health authorities. In fact, the precautions taken are practically the same as they would have been in the old days when nothing was known of the way yellow fever is spread. It is encouraging, however, to learn that the mosquito theory is winning popular recognition, and that the yellow fever outbreak has resulted in the use of a great deal of oil to get rid of the mosquitos. Beaumont has been giving the oil free and the result has been satisfactory. One of the latest applicants was the town of Rado, which got a large supply of oil from Beaumont, used it on all bodies of water around the town and is now absolutely free from mosquitos. That the oil gets rid of the mosquitos is proved by the fact that there is none in the oil fields, formerly infested by them.

**The Office of Coroner's Physician.**—Dr. Albert T. Weston, who has been coroner's physician in New York for several years, has been confirmed in his position by a decision of the Supreme Court in refusing to grant an injunction restraining the coroners from paying Dr. Weston his salary. Justice Barrett says that though Dr. Weston is a holdover from the last Board of Coroners, yet his title is valid and he can be removed only for cause and after a hearing.

**Tuberculosis in a Pennsylvania Penitentiary.**—A Philadelphia Grand Jury has condemned the management of the Eastern Pennsylvania and stated that the place is nothing more than a breeding place for tuberculosis. The plumbing was found to be bad, requiring the constant use of disinfectants. The report further stated that over 60 per cent. of the deaths among the inmates of the penitentiary during the past thirty years have been from tuberculosis, and a bacteriological examination has demonstrated the presence of tubercle bacilli in nearly every one of the prison cells.

**American Society of Clinical Surgery.**—The first meeting of this society is called for November 13 at Baltimore, and November 14 at Philadelphia, under the presidency of Dr. G. E. Brewer of this city. It is proposed that two meetings be held each year, each meeting to be divided between two neighboring cities. The provisional secretary of the society is Dr. J. G. Mumford of Boston.

**Alvarenga Prize of the College of Physicians of Philadelphia.**—The next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, and amounting to about $180, will be made on July 14, 1904, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been published, and must be received by Dr. Thomas R. Neilson, Secretary of the college, on or before May 1, 1904. Each essay must be sent without signature, but must be plainly marked with a motto, and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1903 has been awarded to Dr. William S. Carter of Galveston, Tex., for his essay entitled: "The Relation of the Parathyroids to the Thyroid Glands."

**The Craig Colony Prize.**—A prize of $200 is offered by Dr. Frederick Peterson for the best original essay on the etiology, pathology, and treatment of epilepsy. The conditions to be complied with are as follows: (1) The paper must show original research work. (2) The subject-matter of the essay shall not have been previously published. (3) The manuscript submitted shall be in English and be sent to Dr. Peterson at 4 West Fifteenth street, New York City, before September 30, 1904. The successful manuscript becomes the exclusive property of the Craig Colony. (4) Each paper submitted must be accompanied by a sealed envelope containing the name and address of the author, and bearing on the inside a motto or device which is also to be inscribed upon the essay. The award will be made by a committee of the New York Neurological Society, and the result announced at the annual meeting of the managers of the colony, the second Tuesday in October, 1904. Further information may be obtained from Dr. W. P. Spratling, Sonyea, N. Y.

**Dr. B. Franklin Stahl** has been elected Medical Director of St. Agnes Hospital, Philadelphia, in succession to the late Dr. Wm. H. Parish.

**Medico-Chirurgical College of Philadelphia.**—Dr. Judson Daland has been elected Professor of Clinical Medicine, in succession to Dr. Wm. E. Hughes, resigned; Dr. Hilary M. Christian, clinical professor of genito-urinary diseases, in succession to Dr. E. R. Kirby, resigned, and Dr. Geo. W. Pfromm, clinical professor of applied therapeutics.

**The Carmel Dispensary, New York.**—We are informed that a vacancy has been created in the department of diseases of the eye, in this dispensary, by the resignation of the former incumbent. Applications for appointment may be made to the secretary at the dispensary, 14 Delancey street.

**"Folia Hæmatologica"** is the name of a periodical devoted to hæmatology, the American editor of which is Dr. Charles E. Simon, 1302 Madison avenue, Baltimore, Md. American writers on this subject are requested to send two reprints of their article to Dr. Simon for abstract in the journal.

**"The Journal of Infectious Diseases"** is the name of a new publication established in connection with the Memorial Institute for Infectious Diseases in Chicago. It will be devoted to the publication of original investigations dealing with the general phenomena, causation, and prevention of infectious diseases both of known and of unknown origin. It will appear in numbers issued at irregular intervals, as the amount and nature of the available material will permit. The journal will be edited by Dr. Ludvig Hektoen and Edwin O. Jordan. The cover is ornamented with a device representing a free receptor seizing a wandering toxin molecule.

**A Hospital for Columbia University.**—The trustees of Columbia are considering the advisability of acquiring or building a hospital to be under the control of the medical department, where bedside instruction can be given to the students. At present the Vanderbilt Clinic affords ample opportunity of the study of such diseases as can be treated in outdoor patients, and the Sloane Maternity Hospital furnishes an abundance of obstetric material, but the need of a general hospital for a study of the graver medical and surgical cases is felt. To build and maintain such a hospital it is estimated that a capital of $2,000,000 must be secured.

**The Suppression of Malaria.**—At the recent International Congress of Hygiene, the following resolution introduced by Dr. Patrick Manson was unanimously adopted: "In recognition of the practical importance of the 'mosquito-malaria theory,' the congress shall bring pressure upon all governments in malaria districts for the purpose of, first, causing an examination of civil and military officers as to a practical knowledge of this theory before employing them in such localities; second, of compelling the educational establishments in such districts to add instruction concerning the malaria theory and its practical applications; third, to consider officers who know nothing of this theory or who systematically deny its practical application as unfit for service in malaria districts."

**Increased Rainfall and Lowered Death Rate.**—The London correspondent of *The Sun*, writing under date of October 31, says that the present year has been the wettest in England since 1824, and only two inches of rain are wanted in the remaining two months to break all records. The extraordinary rainfall has been accompanied by a remarkable fall in the death rate. In 1901 the death rate in London was 17.6; Birmingham, 20.5; Bristol, 16; Manchester, 22.1; Leeds, 19.3; Liverpool, 22.3; Sheffield, 20.4. Last week the average in seventy-six great towns dropped to 15.9, and in the two previous weeks they were 15.8. Last week in London there were only 1,333 deaths, against the usual average of 1,505. The deaths from zymotic diseases dropped from an average of 133 to 61.

**Newspaper Responsibility for Abortionists.**—At the October meeting of the Society of Medical Jurisprudence, held on the 12th of the month at the Academy of Medicine, a paper was read by Justice Julius M. Mayer of the Court of Special Sessions on "Criminal Procedure against the Unlawful Practice of Medicine." He gave instances of the difficulties which the prosecution has in convicting illegal and criminal practitioners, chief among which is the practical impossibility of obtaining corroboratory evidence against them. In conclusion he made a strong plea for a strict censorship of advertisements on the part of the great dailies. "The worst agency in New York today," he said, "that helps the man who sells either real or pretended abortion medicine is the newspapers, for they make it possible to ensnare the unwary, the superstitious, and the fearful. I suggest that in the new school of journalism in Columbia there be a chair of advertising, and let it be taught to the young men of the newspaper profession that the first duty of a great newspaper is to censor its medical advertising. If the decent newspapers will assist in the gradual uplifting of public opinion concerning the men and women who engage in these disreputable and criminal occupations, it will be only a matter of a short time until they are driven out of business."

**Philadelphia Neurological Society.**—At a stated meeting, held October 27, Dr. W. W. Hawke exhibited a case of hereditary chorea, occurring in a man about forty-eight years old, whose father, as well as two paternal uncles, had suffered from the same disorder in conjunction with insanity. Dr. Francis X. Dercum exhibited a case of primary neuritic muscular atrophy, occurring in a man twenty-eight years old, in whom the symptoms had developed after an illness attended with chills and fever and headache, and had been present for about eight years. There had been sharp attacks of pain, and subsequently marked disturbance in gait and in station, as well as slighter derangement of coördination in the upper extremities, abolition of the knee-joints, nystagmus and some indistinctness of speech. Dr. Augustus A. Eshner read a paper entitled "Some Graphic Observations on Ankle Clonus." The movements were recorded with the aid of tambours and a revolving kymographion, and a not inconsiderable variation in frequency was found under different conditions—namely, between 6 and 8 in the second, as extremes. In a healthy person the number was found to be between 7 and 7.6 in the second; in a case of hemiplegia between 6.6 and 7.2; in three cases of myelitis between 6.2 and 8; in a case of lateral sclerosis between 5.8 and 6.9; and in a case of probable porencephaly between 7 and 7.3. In some cases reinforcement was evident, both to the hand of the examiner and in the tracings in the form of an increase in the frequency of movement. Dr. Charles S. Potts exhibited a case presenting intermittent clonic movements principally in the right upper and the left lower extremity with weakness. The knee-jerk was enfeebled on the left, and the calf on this side was smaller than that on the right. Fibrillary contractions were evident also in other parts of the body than those named. The nature of the affection was obscure, but it seemed to be in part myelopathic and in part myopathic in origin. Dr. Alfred Gordon read a paper entitled "Tabetic Symptoms in a Girl of Seventeen, Presenting from Infancy Trachial Monoplegia, Probably of Poliomyelitic Origin, with Remarks on Juvenile Tabes," and he exhibited the patient. The association is a rare one, although it is probably only coincidental. It was thought that in the present case the two disorders might be in some way related to hereditary syphilis. Drs. Chas. S. Potts and W. G. Spiller read a paper entitled "A Case of Solitary Tubercle of the Pons Causing Paralysis of Left Lateral Conjugate Movements of the Eyes." The affection of the ocular muscles was thought to be characteristic of an intrapontine lesion and thus contraindicative of operative intervention. Dr. T. H. Weisenburg reported three cases of traumatic lesion of the spinal cord. He exhibited a patient who had been struck by a locomotive and presented symptoms of fracture of a lumbar vertebra or, perhaps, hemorrhage into the cord, and whose most conspicuous symptom, apart from the weakness in the lower extremities, was a steppage-gait. The sphincters and the sexual functions were uninvolved, and the reflexes were exaggerated. In another case a bullet-wound of the cord below the center for the knee-jerk was nevertheless followed by exaggeration of this reflex. In the third case the disturbance was due to a fall from a great height, but remarkable improvement in the symptoms took place. Dr. Weisenburg reported also a case of multiple sclerosis, in which the knee-jerks were abolished, although ankle clonus was present. Drs. Chas. K. Mills and Chas. H. Frazier presented a note on section of the fifth nerve for the relief of the pain in some cases of brain-tumor. The operation has been performed in one case with

satisfactory results, especially with reference to vertigo and vomiting, as well as the headache.

**Manufactured Invalids in the Russian Army.**—At a recent trial in Odessa an exposé was made of an organized plan for making unwilling conscripts in the Russian army unfit for service. This was done in a multitude of ways, by tampering with the ears or eyes, by inoculating with disease germs, etc. The price paid varied from a few rubles up to as much as four hundred, or about $200.

**Anti-corset Laws.**—Freak health legislation is evidently not confiend to America, for Dr. Maréchal of Paris is urging the passage of a law making the wearing of a corset by any woman under thirty years of age an offense punishable by three months' imprisonment if the woman is of age, and a fine of $20 to $200 imposed on her parents or guardians if she is under age. A woman who died suddenly in Buffalo a few days ago was found, on post-mortem examination, to have been killed by a corset-steel which had pierced the heart. This would probably be accepted by Dr. Maréchal as a weighty argument in support of his proposed legislation.

**Obituary Notes.**—Dr. JULIAN J. CHISHOLM died at his home in Petersburg, Va., on November 1, at the age of sixty-five years. He was a graduate of the Medical College of South Carolina in the class of 1850, and for many years practised in Baltimore, where he filled the chair of diseases of the eye and ear at the University of Maryland, and was surgeon-in-chief to the Presbyterian Eye, Ear, and Throat Charity Hospital.

Lieut.-Col. WILLIAM E. WATERS, Deputy Surgeon-General U. S. A., retired, died suddenly at his home in Washington on October 26, at the age of eighty-nine years. He was born in Washington and entered the Civil War at its outbreak as Assistant Surgeon of the District of Columbia Volunteers. Appointed to the Regular Army in 1862, he rose to the grade of Lieutenant-Colonel and Deputy Surgeon-General, with which he was retired in 1897. He was brevetted for faithful and meritorious services in the Civil War.

Dr. SIMON POLLAK, one of the oldest physicians in St. Louis, died recently at his home in that city, at the age of eighty-nine years. He was a native of Bohemia, and obtained his medical degree from the University of Vienna in 1835. He began the practice of medicine in St. Louis ten years later.

Dr. JOHN C. NEVINS died on October 27 at his home in Summit Hill, Pa., at the age of fifty-seven years. He was graduated from Jefferson Medical College in the class of 1873.

Dr. BENJAMIN A. ANDREASS died at his home in Bethlehem, Pa., on October 27, at the age of forty-four years. He was graduated from Jefferson Medical College in the class of 1888.

---

**Health of Chicago.**—Dr. Arthur R. Reynolds thus defends the work of the present health department of Chicago. During the six years, 1891-1896, immediately preceding the present administration of the department, a total of 152,424 deaths were reported in Chicago; during the six years, 1897-1902, of the present administration, the total deaths reported were 145,907, or 6,517 fewer deaths in upward of 360,000 more population. The reduction is even greater among infants and young children—the acknowledged test of the efficiency of a sanitary administration. During the first period there were 68,008 deaths under five years of age; during the second period there were only 49,360 such deaths. This is a reduction of 18,648 deaths of the under five in the increased population above shown.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

THE SOCIETIES—HEMORRHAGIC PANCREATITIS—GASTRIC ULCERATION—KING'S COLLEGE AND HOSPITAL REMOVAL—MR. CHAMBERLAIN'S GOUT—HOSPITAL SATURDAY—DEATHS OF SIR GEO. DUFFY AND MR. LAWSON.

LONDON, October 16, 1903.

THE societies are now in full work again. At the Medical the President, Dr. M. H. Hall, opened the session with an address giving a retrospect of papers communicated to the society from its beginning, on diseases of the respiratory and circulatory systems. This is a hint that others might follow up without necessarily going so far back. The plan would afford an excellent opportunity for a critical examination of progress. At the Gynæcological, the President, Dr. Heywood Smith, opened with notes of the cases of some specimens he brought. Specimens were also exhibited by other members who gave an account of their respective cases. The Harveian Society met last night and there are other meetings this evening. Sir Wm. Job Collins gave an address on Tuesday at the Society for the Study of Inebriety. He discussed institutional from an administrative rather than a therapeutical point of view.

The pancreas has not of late obtained much attention in comparison with that bestowed on other viscera, but at the opening meeting of the Clinical Society, the president, Dr. F. Taylor and Mr. A. Bowlby, each made a communication concerning it. Dr. Taylor's case was that of a man of sixty-eight years, the subject of emphysema and bronchitis, who had drank, instead of water, a solution of oxalic acid of unknown strength and had been given emetics which acted. Later he became collapsed, tremulous, and cyanosed. The next day he went home, but two days later returned to the hospital. He was then cyanosed, feeble, with rapid pulse and breathing. Bronchitis was worse and became the chief feature of his illness, which closed fatally twenty days later. At the post-mortem there was emphysema, purulent bronchitis and pleurisy; ten ounces of blood were found in the great omentum; the pancreas was in a state of interstitial, hemorrhagic pancreatitis, enlarged, hard, infiltrated with blood; no peritonitis; no fat necrosis; kidney slightly granular. The points in the case are the relation of the condition of the pancreas to the state of the chest and the oxalic acid poisoning and the complete latency of the pancreatic lesion which was, perhaps, masked by them.

Mr. Bowlby's case was in a man of forty-one years seized with abdominal pain and vomiting. For the next two days he complained of flatulency and constipation: the vomiting continued, abdomen tender, but no swelling perceptible. Bowels acted well to enemata. On the third day he became delirious, and from that time had delusions. Urine scanty. On the eighth day he had a sudden attack of pain with severe vomiting, followed by abdominal distension and obstruction. The abdomen was opened and showed some general peritonitis with old adhesions, but no mechanical obstruction. A coil of small intestine was opened to relieve the distension, but the patient died. At the post-mortem a very large hemorrhage surrounded the pancreas and extended down to the pelvis. The pancreas itself was engorged with blood and there was general peritonitis.

Mr. Barker said that in two cases he had noticed the amount vomited was enormous, and asked if this were so in the cases before the society. Mr. Bidwell had operated on a case he took for pus in the gall-bladder, but he found a large collection behind the foramen of Winslow, which escaped. The vomiting ceased and the patient was well in a month. Not long afterward he died with a temperature of 104°, so he thought a fresh collection had formed, but no post-mortem was permitted.

At the same meeting the indications for operating in gastric ulcer were the subject of comment arising out of the account of a case by Sir D. Duckworth. His patient was admitted with a history of severe pain after food for the previous three weeks and prior to that indigestion for about eighteen months. On the day of admission several attacks of bleeding occurred for the first time. Patient became blanched with abdominal distension and epigastric tenderness. Rectal feeding was tried and small doses of adrenalin chloride by the month. Whey was subsequently given in two-ounce and later four-ounce doses and a pint of saline solution daily per rectum. Later on it was clear that active gastric hemorrhage was going on, and the stomach was opened by M. Butlin. No ulcer was found, but in the greater curvature near the pylorus the mucous membrane for several square

inches was pink, markedly different from the other part, which was ivory yellow. At various points on the pink area were slight excoriations, fissures, and tiny points from which blood slowly oozed, nine of these points were ligatured with fine silk thread with a purse-string suture. The remainder of the operation need not be described. The next day temperature fell from 101° to 99°. The condition of the gastric mucous surface in this case is believed by Drs. F. J. Smith and Mansell Moullin to be the starting-point of most, if not all, gastric ulcers, and it is probable that if the hemorrhages from it prove fatal in any instance the actual lesion could not be detected after death.

Mr. Moullin, who brought the subject before the society three years ago, said he had operated in eleven cases. He discussed the appearances of the membrane during life and after death. Repeated severe hemorrhages, especially if associated with intense anæmia, were the indications for operation which should not be delayed until the patient was too exhausted. It was said only 3 per cent. of gastric ulcers were fatal, but no one proposed to operate on all. Not more than 10 per cent. were serious enough for surgical measures.

Dr. de H. Hall did not think 10 per cent. were serious. He had had many cases at the hospital but not one fatal. Only once had he advised an operation.

Mr. Barker recommended gastroduodenostomy, which tended to bring about cessation of bleeding, gave the stomach rest, and enabled it to empty itself.

Mr. Wallis advised an early opening to seek the bleeding spot.

Dr. Louis Pasteur spoke of the difficulty of diagnosing erosive from other ulceration when hemorrhage was actually going on. In erosion bleeding seemed continuous, in chronic ulceration it often subsided under treatment.

Mr. Keetley said it was often impossible to find the bleeding point. In one case he found the ulcer adherent to the diaphragm. He separated them and packed the cavity. A few months later gastroenterostomy was required. He advocated this operation, as it rested the stomach and made it aseptic. A bleeding ulcer might also be packed, or a simple jejunostomy done, as proposed by Ferner.

Mr. Butlin agreed that gastroenterostomy was often efficient. The difficulty of finding might depend partly on the surgeon and partly on the ulcer. In some cases small nævoid spots might bleed to a fatal issue. He advocated opening the stomach, and then if the spot could not be found, performing a gastroenterostomy. But it was always best to locate the spot.

Sir D. Duckworth thought erosion had a different appearance after death. He found pyrosis a common symptom in chronic ulcer. Prolonged anæmia was the chief cause, bad food and stays contributing their influence.

The question of removing King's College Hospital, which has been agitated for more than two years, has been decided in favor of the step. The council and the committee, as I have previously told you, are in favor of the change, and on Monday a meeting of the governors was held to sanction it. The Staff, too, is in its favor. It is not surprising that there should be opposition, and a letter signed by ten members of the committee has been circulated, deprecating the removal. Others regret for reasons of long association, but acquiesce on the necessity.

At the meeting the Hon. W. F. D. Smith presided and remarked that he fully shared the feelings of those who regretted the break in the many local associations which gathered round the present position, he was convinced that removal to a more suitable site would be fraught with benefit to the hospital, the medical school, and London generally. The question of removal had been carefully considered by more than one committee of inquiry. There must be a majority of three-quarters in favor of the scheme before the bill could go to Parliament.

Dr. Buzzard moved that "this court approves the proposal to remove King's College Hospital to a site in South London." The resolution would have been moved by Lord Lister and seconded by the Bishop of Exeter, but both had been prevented from coming. Fifty years ago, Dr. Buzzard said, he was a resident medical officer and the district was then vastly different. The existing buildings lacked many requirements, and it was in the interests of the public and the school to remove to the suburbs.

Mr. Awdry seconded, and held that in its present position efficiency could not be attained. Some had said the school was not necessary, but he maintained that where there was a school the patients benefited by the services and teaching of great professional men.

The opponents of the scheme took the line that there were still many poor in the district, and that the transformation was far from complete and would not be for two years. An amendment was proposed accordingly to postpone the decision for that time, but it was lost. The resolution was passed and a joint committee of the council of the college and committee of the hospital were authorized to acquire a suitable and adequate site. The council and committee were further authorized to apply to Parliament for such powers as were found necessary to carry out the scheme.

As a "memorial" of the hospital a picture just published seems opportune. It is a lithographed sheet, 3 feet by 2, the center occupied by a view of the exterior of the building. This is surrounded by drawings of the interior of wards, laboratory, and chapel. Then there are portraits of eminent members of the staff, past and present. *e.g.* Watson, Fergusson, Budd, Todd of the deceased, and among those still surviving, Lister, Beale, Rose, Watson, Cheyne, etc.

Mr. Chamberlain occupies so large a place in the country just now that his temporary illness seemed the medical news of the week. It was only a fit of gout, to which he is rather subject, keeping him in bed for a day or two. It was precipitated by his great exertions in the campaign he has begun. He was up again yesterday, but limping.

Hospital Saturday was duly observed on the 10th inst. The street collections have now been omitted for six years without injury to the fund. The usual collections took place in the workshops, public institutions, and various places of record. Many boxes were also placed outside shops, and passers by often availed themselves of the opportunity of contributing through them. Last year, as I lately told you, was the best year of this fund, which reached £22,964.

The new laboratory of the London School of Tropical Medicine is completed and is splendidly equipped for its work. The number of students entered this session is the largest the school has ever had. The new museum and lecture room will shortly be ready for use.

Sir George F. Duffy, ex-President of the Royal College of Physicians in Ireland, died on Tuesday, aged sixty. He was Inspector of Examinations for the General Medical Council, and at the last meeting of that body much regret was expressed at the illness which interrupted his work. On account of health he lately resigned his hospital appointments. Physician and Lecturer on Clinical Medicine at the Royal City of Dublin Hospital, Professor of Materia Medica at Red Cross Society, he served as examiner on the Conjoint Board and at University of Dublin, of which he was a graduate, a medical scholar, and a medical exhibitioner. He was author of "Suggestions for a Plan of Taking Notes of Medical Cases," which reached a second edition in 1890. He edited "Griffith's Materia Medica and Pharmacy," and contributed valuable papers to the journals and the Transactions of the Irish Academy. Among the latter I may recall his paper on the connection of acute diabetes with disease of the pancreas and another on stenosis of the valves of the heart.

Mr. George Lawson, surgeon-oculist-in-ordinary to Queen Victoria, died on Monday at the age of seventy-two years. His early qualifications date from 1852. In 1857 he became a Fellow of the Royal College of Surgeons, of which he has been one of the councillors. He acted as assistant surgeon to the Rifle Brigade in the Crimea, being present at the battles of the Almar and Inkerman and the Siege of Sebastopol. He taught anatomy at the old Grosvenor Place School, and surgery at the Middlesex Hospital. But his most important work was at the Royal Ophthalmic Hospital in Moorfields (now removed), of which he became consulting surgeon, as he did also of the Middlesex Hospital. His "Manual of Diseases and Injuries of the Eye" reached its fifth edition in 1885. His "Sympathetic Ophthalmia" appeared in 1865. His "Injuries of the Eye, Orbit, and Eyelids," which dealt with the immediate and remote effects in 1867. His Crimean experience gave rise to a work "On Gunshot Wounds of the Thorax," 1858, a subject also treated in a volume by the late Dr. Patrick Fraser of the London Hospital, who also went to the Crimea and subsequently returned to his position as physician to the London Hospital. Many of Mr. Lawson's most valuable contributions to Ophthalmic Surgery appeared in the Reports of the Royal London Ophthalmic Hospital from 1861 onward. As a teacher he was held in the highest esteem. As a man his friends mourn as those who do not expect to meet his like.

---

**Hour-glass Stomach.**—Mr. B. G. A. Moynihan, Leeds, England, does not concur in the general view that this condition is "congenital" and acquired. He believes that there is no evidence whatever which will establish the claim of those who declare that the disease is often congenital in origin. Acquired hour-glass stomach may be caused by (1) Perigastric adhesions; (2) ulcer with perforation and anchoring to the anterior abdominal wall; (3) chronic ulcer generally at or near the middle of the organ—malignant disease

# Progress of Medical Science.

*The Boston Medical and Surgical Journal, October 29, 1903.*

**Pneumothorax Associated with Fracture of the Ribs.**—Fred. T. Murphy describes two cases of this nature. One was in a man, forty years of age. He had been thrown from a truck and run over by the hind wheel. His condition at first was a mild state of shock. In the right axilla there was some emphysema. The left shoulder was dislocated. His color and respiration were good enough to warrrant giving ether for the reduction of the dislocation. The next morning his condition was much worse. His face was cyanotic, the respirations rapid and labored. There was tympanitic resonance over the right side with loss of respiratory sounds and fremitus. The heart was slightly displaced to the left. The pulse was good. His state became alarming. The chest was punctured below the angle of the scapula. The extreme dyspnœa ceased with the outrush of air, and the color returned. Aspiration afforded even greater relief and was kept up for half an hour. Cyanosis was relieved, and the heart returned to its normal position. Five days after aspiration the lung had returned to the normal position. The emphyema cared for itself. On the ninth day he was discharged well. The second patient was a child nine years old. He had been thrown from a bicycle. He was in poor condition. Both sides of the neck and the left back were markedly emphysematous. The condition was rapidly becoming extreme, and a large trocar was inserted on the left at the angle of the scapula. A rush of air followed, and the dyspnœa was relieved and the cyanosis disappeared. All but a trace of the emphysema and pneumothorax had disappeared by the fourth day.

*Journal of the American Medical Association, Oct. 31, 1903.*

**Calcareous Degeneration of Corneal Cicatrices.**—H. Moulton reports two cases. The author says that all leucomata involving the iris, presenting a chalky area sharply outlined in contrast with the rest of the opacity, may be and should be cut into, even though the surface seems smooth. At the first examination in the cases reported it was evident that the deposits were areas of degeneration probably calcareous. They were not removed at first because, first, neither the probe nor magnifying glass revealed any break in the smoothness of the organic tissue overlying them; second, the symptoms were not such as usually are caused by a superficial foreign body, being in one case those of asthenopia, in the other more like those of glaucoma; third, there was some fear of exciting undue reaction by digging into an adherent leucoma, for merely exploratory purposes. Later, the deposits in one case became partially uncovered, and gave rise to foreign body symptoms, at once indicating the proper procedure.

**Talma's Operation in Cirrhosis of the Liver.**—The paper of M. L. Harris consists of the reports of four more cases in addition to those previously reported by him (two in number). Of the six cases five were dead inside of a month after operation and one was alive, but without improvement, five months after operation. The five cases that died were undoubted cases of alcoholic cirrhosis; the one that was living at the end of five months was in all probability due to syphilis. All of them were far advanced when operation was undertaken, and, it is not claimed that any material improvement followed the operation. The author believes that the congestion of the portal radicles is not the sole cause of the ascites, but that the changes in the peritoneum of a chronic inflammatory nature are instrumental in its production, especially during the terminal stage. In order to obtain the full benefit of the operation it should be performed early, at the first appearance of ascites, or even to anticipate the ascites, if possible. In cases showing jaundice or symptoms of cholæmia, cholecystostomy should be performed at the same time.

**The Morphology and Biology of the Parasite from a Case of Systemic Blastomycosis.**—F. J. Otis and N. Evans offer the following summary of their work based on the case reported by Ormsby and Miller (*Journal of Cutaneous and Genito-urinary Diseases*, March, 1903): (1) This case was one of systemic blastomycetic infection and belongs to a class of which but a very few instances have been reported. (2) Parasites were demonstrated in the blood post-mortem, and dissemination evidently took place through this medium. (3) The lymph glands were remarkably free from infection. (4) In the lesion the parasites were found in immense numbers, and the inflammatory reaction in the tissues were of a remarkably slight degree. (5) The leucocytes of the blood and certain tissue cells contained large quantities of round pigment granules. (6) Parasites grew in the tissue only by budding, the forms appearing from five to fifteen microns in diameter; in artificial culture by segmented mycelia, lateral conidia, and in very old cultures a few budding forms. (7) There was a definite order of development of the parasite in the tissue, the younger forms having a densely staining protoplasm undergoing active cell division by gemmation; the older forms not deeply staining and not actively dividing, and containing spore-like bodies. (8) From the findings in the tissue it seemed evident that sporulation occurred, five to fifteen spores developing in each cell where they were seen. (9) Organisms derived from teased tissues were observed in hanging drop to produce mycelia within a few hours after they were removed from the tissue. (10) The effect of exposure to the *x*-rays was negative. (11) The effect of the actinic ray was doubtful because the element of heat was not eliminated. (12) The cultures covered with cedar oil paper died within one month. Those exposed for one week were completely inhibited from growth, but were not dead. (13) The organism fulfilled the laws of Koch, guinea-pigs being more susceptible than rabbits. (14) The organism grew readily on all forms of artificial media used. (15) In gelatin liquefaction was produced after one month.

*Medical News, October 31, 1903.*

**Skin Lesions Associated with Rapid Growth of Long Bones.**—W. P. Northrup reports the case of a boy of seventeen years who, during a siege of typhoid fever, grew in height. For two years he grew to an unusual degree. His knees, were never swollen. There are scars across his knees which he is sure were not there during his convalescence. He cannot recall when they first appeared. When first seen they were pinkish, like wheals or welts made by a switch. There are no other similar scars on his limbs or body. The author quotes Jules Comby, Charles Norris, and Bradshaw, who have observed the same phenomenon. He believes that the skin cannot keep pace with the bones, and frayings result.

**Caffeine in the Treatment of Alcoholic Toxæmia.**—Arthur J. Hall declares that the physiological antagonism of caffeine and alcohol has been recognized. A most important fact to the therapeutist is the fact that caffeine, given in doses of one or two grains every one, two, or three hours, will usually, in twenty-four or forty-eight hours, so effectually quench the thirst or craving for alcohol that most confirmed habitué's will voluntarily abandon its use. The writer then cites several cases in point. He does not advocate caffeine as a specific in all cases of alcoholic toxæmia to the exclusion of all other remedies and measures. But he is strongly inclined to credit caffeine with a physiological antagonism to alcohol as clearly marked as that between belladonna and opium. When this is established, the contention that alcoholism is a disease will be abandoned, and the fact that it is a toxæmia must be admitted.

*New York Medical Journal, October 31, 1903.*

**The Treatment of Diseased Faucial Tonsils in the Adult.**—E. W. Davis counsels the removal of all the diseased tissue. There is no one operative procedure that suffices for every case. Personally he advocates the use of the tonsil punch, preferring the Freeman model.

**Conservative Gynecological Surgery: Its Practical Results.**—H. C. Coe reviews the changes of the last few years with reference to ideas as to the proper limits of pelvic surgery. His own aim has been to so operate as to preserve the function of menstruation in order to avoid the physical and psychical disturbances attending the artificial climacteric. In regard to remote results the author declares that the chances of a recurrence of the original pathological conditions vary according to the character of the adhesions and exudates found at the first operation and the extent of the denuded surfaces left within the pelvis. No certain method has yet been discovered of preventing the reformation of adhesions, or predicting in what cases they will give us future trouble. If pus is present and foci of infection are left, the result is even more doubtful, in spite of the gauze tampon. Coe regards resection of the tubes as a rather uncertain procedure. His practice in every doubtful case is to exsect the entire tube, suturing the uterine wound and broad ligament with continuous catgut. The ovaries are then dealt with separately, and are secured near the uterine corona in order to avoid prolapse and fixation in the cul-de-sac by fresh adhesions. But even then we have been obliged to remove them subsequently on account of persistent pain. The number of secondary operations, generally involving extirpation of the uterus, is a proof of the uncertainty of the prognosis. Results as to belief of symptoms following the various operations are uncertain. If pain is relieved the patient is generally satisfied and is little concerned about menstruation, ovulation, or pregnancy.

**A Consideration of the Pathology and Treatment of Cancer.**—L. Weber refers to various theories of the disease, declaring that certain pathological facts speak against its parasitic origin, especially the cases in which the growth starts from congenital inclusions or aberrant groups of cells. External causes do no more than excite cell proliferation, and consequently there must necessarily occur abnormal changes in the substance of the cell by which its physiological structure is changed. Such product of cellular action are both stimulating and toxic. The cells may lose from various causes some of their physiological influences. Such causes include hereditary or acquired weakness and disturbance of the finer nerve adjustments. In regard to treatment the author cautions against too hopeful statements as to probability of non-recurrence. The best surgical procedures will not guard against this. He is in accord with the general opinion as to the good effect of actinic rays on superficial malignancy. In general every operable growth should be removed early and radically. By rapid and skilful operating and the avoidance of all unnecessary bruising and of pressing into the affected parts, by which cancer cells may be driven and dispersed into neighboring tissues, the prospects of smooth healing and of non-recurrence are greatly improved. Following the recovery from the operation, the patient should return to the care of his regular medical attendant. Much can be done for him by proper diet, hydrotherapeutics, frequent exposure of the body to sun or electric light, arsenic, iron and quinine, etc. These all increase the constitutional resistance against the carcinomatous toxins and make a soil unsuited to the proliferation of degenerated cells, or to the growth of cancer parasites.

*American Medicine, October* 31, 1003.

**Volvulus of the Stomach.**—C. D. Spivak concludes: (1) The occurrence of volvulus of the stomach is a possibility beyond a doubt; this condition should be borne in mind when making a differential diagnosis between pyloric obstruction, occlusion of the bowels. poisoning, cyclic vomiting, cholelithiasis, peritonitis, etc.; surgeons should be ready to operate when necessary, and not forget to empty the stomach of its contents. Authors should devote some space to this condition in their textbooks. (2) Volvulus of the stomach occurs in all ages and in both sexes. (3) Digestive disorders may be considered as etiological factors. (4) From a pathological standpoint volvulus may be divided into that due to organic changes, and that in which no visible organic changes have taken place. (5) The characteristic symptoms are: Sudden onset; distention which begins in the left hypochondriac region and gradually increases in size; a tumor which gives, on percussion, a tympanitic sound; vomiting or regurgitation immediately following ingestion of food or drink; no belching, no escape of flatus; inability to pass a sound into the stomach. (6) When the condition is recognized, early operative interference is indicated, and recovery is almost certain.

**The Dietetic Treatment of Chronic Nephritis.**—J. M. Anders believes that there is no disease in which a judicious management of the diet is of greater practical importance to the patient than chronic nephritis. A dietary that fails to meet the requirements of nutrition, plus the loss of albumin which takes place through the kidneys, amounting to from 1 to 3 dr. daily, is inadequate, and certain to be followed by the evidences of malnutrition. Efforts to lessen the degree of albuminuria at the expense of the quality of the blood and general nutrition are not so much blessings as evils. The effects of insufficient diet react preiudicially upon the kidney lesions, hastening, rather than postponing, the fatal issue. Medicinal measures are of value only in a small minority of cases. Ordinarily an exclusive milk diet is not advisable. Milk does not furnish sufficient iron or carbohydrates to sustain the system. Foods which contain a large proportion of nitrogen, such as meats, must be somewhat restricted in amount. Fats in moderate quantity are allowable and often beneficial. So whole milk is, as a rule, better than skim milk. Many authorities think that red meats are not more injurious than white. Food should be selected that furnishes the smallest residuum to be eliminated through the kidneys Whole milk diluted should make up a considerable part of the diet, while, as a rule, meats should be restricted, and fruits. green vegetables, and rice should be given more freely. The meals should be small and taken at three-hour intervals. The writer then speaks of the value of chemical examination of the products of elimination, of cryoscopy and of systematic blood examinations.

*The Lancet, October* 24, 1903.

**On the Use of Pure Carbolic Acid in the Treatment of Smallpox.**—A. E. Brindley and F. W. Bonis have used the remedy in thirty-five cases, of which twenty-two were of a severe type, being mostly confluent, more than half of these being in unvaccinated subjects. Five of the cases proved fatal, two of which were children suffering from scarlet fever, while the third was one of malignant smallpox with minute subcutaneous hemorrhages and death during the papular stage. At first the authors confined the remedy to the face and hands, with the idea of diminishing the scarring, but in order to obtain the best results it is necessary to apply it carefully over the whole body, according to the following method: The pure acid in a liquefied state is applied to the vesicles over a limited area with a small camel's-hair brush, the application being made on successive days. On the first day the face and neck are selected for treatment, on the following day the hands and the arms, then the lower extremities, and, finally, the trunk. The effect of the acid is seen in the rapid shrivelling up and scabbing of the vesicles. A second or third application may be made, if necessary, over certain parts of the body. An important detail of the treatment is to secure the early removal of the scabs, either by an oil poultice or otherwise, as this tends to prevent subsequent abscess formation. A noticeable feature is the mildness of all the secondary symptoms of those coincident with the maturation of the pustules.

**On the Effect of Perforation of the Colon by Small Foreign Bodies, Especially in Relation to Abscess of an Epiploic Appendage.**—J. Bland-Sutton states that the amount of foreign material swallowed daily in the food is far greater than one would imagine. Many foreign bodies give no symptoms whatever as they pass through the bowel without lodgment. Many of the smaller ones lodge in the epiploic appendage, a result favored by the disposal of the fat in the subserous layer of the colon. The fatter the patient the less likely is a sharp foreign body to enter the general peritoneal cavity, and the more likely to enter an epiploic appendix where it may set up suppuration. Two illustrative cases are described. From results observed in these and other cases, the author is led to believe that there can be little reasonable doubt that in some instances at least the cause of the tumors of the abdomen which disappear spontaneously after operation is a minute foreign body which has perforated the cæcum, the colon, the sigmoid flexure, or the rectum. In many cases the foreign body becomes completely surrounded and isolated by hardened fecal matter, and this indicates very satisfactorily the way in which angular and dangerously pointed bodies may traverse the colon and be safely ejected without harm to the host—that is, they probably serve as a nucleus for the conglomeration of fecal matter, and, carefully isolated in this way, they escape through the anus without injuring the bowel wall in the neighborhood of the sphincter, for, common as anal abscess is, it stands numerically in very small proportion to the great number of small foreign bodies which are daily ingested and egested.

**On the Value of Saline Infusion in the Treatment of Enteric Fever.**—The patient of D. G. Marshall was a woman, aged twenty-five years, with a typical typhoid. In the third week, when she was evidently sinking from heart failure and there was no response to any of the usual heart stimulants, twenty ounces of saline fluid were injected into the areolar tissue surrounding the right breast. This was followed by some improvement and was repeated on several occasions, thirty ounces even being used. The patient passed through several crisis from hemorrhage, but eventually recovered. The author thus describes the apparatus used: To one end of a three-foot piece of No. 3 rubber tubing a trocar and cannula were attached, the other end being tied to the nozzle of an ordinary two-ounce glass male syringe from which the piston had been removed. The whole was rendered aseptic by immersion in a solution of biniodide and subsequent flushing with hot sterilized water. The fluid was prepared by adding salt to water boiled in a tin kettle, brought to boiling point, and cooled to 100° F. It was introduced into the areolar tissue round the breast, the time occupied for twenty-five ounces being about ten minutes, only one insertion of the cannula being necessary on each occasion. An assistant holding the syringe uncovered in his left hand kept it about two-thirds full from the kettle held in his right hand. The advantages of this method are: (1) The amount of fluid in the syringe can easily be seen; (2) by raising or lowering it the pressure can be increased or diminished; and (3) by firmly holding the syringe the temperature of the fluid is kept at, or about, blood heat. Any diminution in the temperature is at once noted and can be rectified by passing the kettle a few times over the flame of a spirit or paraffin lamp. No local irritation followed any of the injections.

*British Medical Journal, October* 24, 1903.

**High-frequency Currents in the Treatment of Some Forms of Deafness.**—J. C Fergusson explains that his method of treatment by "high-frequency" currents consists in keeping the patient for ten minutes in the large autoconduction solenoid and then exposing him for five minutes to d'Arsonval's bipolar effleuve with the brush electrodes held opposite both ears, but at such a distance as to preclude sparking. He reports several cases, in each of which the patients had been deaf for a long time. The hearing was improved in every case, and in the only one in which sufficient time had elapsed for a full course of treatment it was completely restored. The writer believes that this new method of treatment of deafness is full of promise and deserves a thorough trial at the hands of medical men.

**Pathology of General Paralysis of the Insane.**—W. Ford Robertson concludes that the bone marrow of the general paralytic presents chronic changes of a severe character. The bones show various forms of alteration, but are commonly thickened and sclerosed. The medullary part is usually diminished by overgrowth of bone. Various clinical facts, when taken together, tend to show that the general paralytic is suffering from a bacterial toxæmia. These consist in the rises of temperature, the leucocytosis, and the disorders of the digestive functions, and in the chronic sore throat and septic condition of the mouth, and in the evidence of chronic bronchitis. There are severe changes in the alimentary and respiratory tracts of the character of those that are produced by the prolonged action of bacterial toxins. These changes consist in chronic catarrhal conditions, shown by proliferative, atrophic, and sclerotic lesions. The stomach in some cases shows little or no alteration. The writer has always found the ileum affected. The tonsils are frequently enlarged and their crypts filled with purulent matter. Often they are very atrophic. Even then they often contain cavities filled with pus. The trachea and bronchi generally show distinct chronic inflammatory changes. The lungs often show evidences of long-standing bacterial infection. The writer makes no claim that this hypothesis has been established; he has merely stated a series of facts which harmonize with it.

*Deutsche medicinische Wochenschrift, October* 8, 1903.

**Heart Syphilis and Tabes.**—Schuster finds that in an overwhelmingly large proportion of cases syphilis of the heart affects the aortic orifice. The fact that tabes and aortic lesions are often associated leads him to conclude that in most cases the two conditions have a common origin in a syphilitic infection.

**Hemorrhagic Erosions of the Stomach.**—Elsner made microscopical examinations of the washings obtained from the stomachs of one hundred and twenty fasting patients in order to determine what degree of importance attaches to the finding of the bits of gastric mucous membrane described by Einhorn, and considered by him and others to be typical of a condition termed "hemorrhagic erosions of the stomach." Healthy stomachs did not yield the structures in question, and they were very infrequent in cases without inflammatory change. On the other hand, 35 per cent. of the cases of gastritis with diminished secretion furnished the bits of tissue with more or less constancy. In most of these cases the presence of the mucous membrane exfoliations was not responsible for any change in the clinical picture, and it does not, therefore, seem advisable to accept them as the groundwork for a new clinical division. In only three of the cases was the presence of the exfoliations accompanied by the characteristic pain, and the author considers it advisable to postpone the adoption of the term until its clinical identity has been proven by autopsy.

**The Etiology of Pulmonary Emphysema.**—Golubow discusses two factors in the production of this condition which are frequently overlooked by the clinician. Several cases of his own and from the literature have shown on autopsy that what was supposed to be simply a chronic bronchitis with emphysema was accompanied by a considerable dilatation of the thoracic aorta. A closer scrutiny of cases, apparently of similar type, has led him to conclude that the aortic lesion is much commoner than is supposed, and is the primary cause of many cases of emphysema. Even small dilatations of the aorta can produce severe spasmodic cough either through irritations of the vagus, the recurrent laryngeal nerve, or direct pressure on the trachea, and such a condition after a time can easily give rise to emphysema as well as to a chronic catarrh of the upper-air passages. A careful physical investigation, together with *x*-ray examination, will often reveal such a condition of the aorta in elderly persons, and the author believes that the tendency to require all the classical symptoms before venturing a diagnosis of thoracic aneurysm should be discouraged. Another condition often underlying emphysema, particularly in younger individuals, is a congenital anomaly of the ribs. Not rarely the seventh, sixth, fifth, and even the fourth rib, have the same form of attachment to the sternum as the false ribs, most of the front of the chest then being formed of a single cartilaginous plate. Under these conditions respiration is much impeded and emphysema often results.

*Deutsche medicinische Wochenschrift, October* 15, 1903.

**Influenza, Appendicitis, and Their Interrelation.**—Schultes reports three cases in which appendical symptoms accompanied influenza and appeared to form a manifestation of this infection. One of these was so severe that operation was seriously considered, but deferred in view of the favorable course run by the two preceding ones, with the result that the symptoms subsided and complete recovery took place. While the author believes that infection of the appendix through influenza bacilli can take place in the manner detailed by Adrian, who has recovered the organism from appendical pus, he is not in accord with the opinions of Faisans and other French writers who hold that appendicitis in most cases has influenza as its real cause.

**Pharyngeal Tuberculosis in Children.**—According to Schoetz, only seventeen cases of this condition have appeared in the literature, and he adds two more to the number. In one the condition at first exactly simulated diphtheria, and the diagnosis was made only after the long duration of the disease and absence of diphtheria bacilli had excluded this affection. In both cases there was pharyngeal ulceration with thick membrane formation and intense dysphagia. Pulmonary involvement speedily took place and death ensued in a few months. The author does not believe that tuberculosis of the pharynx occurs as a primary condition, but rather that careful inquiry will always elicit previous symptoms in the abdomen, ears, lungs, etc., and that the localization in the pharynx is only the expression of a general miliary invasion.

**Angina Vincenti.**—Hess describes this disease, which is a form of membranous-angina that has as yet received but little attention, though it is growing commoner and not rarely accompanies other infectious diseases. The disease is characterized by tonsillar exudate, cervical adenitis, dysphagia, and fever; it resembles diphtheria, but its course is short and benign. It also resembles syphilitic angina. The causative agent is the bacillus fusiformis, a spindle-shaped organism 6–12 $\mu$ in length, which occurs in symbiosis with a spirillum of about twice the length. Neither form has yet been cultivated. Two clinical types are observed. (1) The rarer croupous form, which is very mild and runs its course in from two to three days, and (2) the ulcerative form, which may last for weeks, and is accompanied by the formation of deep ulcers. Diphtheria and syphilis may exist conjointly with the disease, and must always be excluded before the diagnosis is made. The treatment consists of chlorate of potassium gargles, chamomile tea, local applications of Lugol's solution, 5 per cent. silver nitrate, balsam of Peru, and methylene blue.

*Berliner klinische Wochenschrift, October* 12, 1903.

**Angina Complicated with Acute Thyroiditis.**—Lublinski adds to the lately reported instances in which inflammation of the thyroid has appeared as a complication of such diseases as typhoid fever and pneumonia, four cases of angina accompanied by non-suppurative thyroiditis. All of these were in women from twenty to thirty years of age, and the complication appeared on the fifth or sixth day after the fever due to the primary condition had subsided. The symptoms were moderate rise of temperature, well-marked local tenderness, swelling, but no redness, and a considerable rise in pulse-rate, thought to be due to pressure on the vagi. From two to eight weeks were required before the swelling entirely subsided. The author assumes that the angina was of rheumatic origin, and the thyroiditis a metastatic inflammation. The benign course of the disease is in accord with Godlee's observation that rheumatic thyroiditis does not suppurate.

**Urticaria Following Endonasal Application of Adrenal Extract.**—Rosenberg placed a small bit of cotton saturated with adrenal extract in the nasal passage of a young girl to reduce the swelling of the turbinateds for diagnostic purposes. The preparation used was made according to his own formula previously published. The next day the patient returned saying that some hours after the application a rash had appeared over the arms and body, which had itched so intensely as to keep her from sleeping. It disappeared after about eighteen hours. A week later another application of the drug was made with a like result,

the urticarial wheals persisting till the following morning. Water and cocaine applied in a similar way failed to produce any symptoms. The author is in doubt as to whether the condition should be considered as a medicamentous urticaria or held to be of reflex nature. In favor of the latter view is the fact that, although the preparation was odorless, the patient said that its application was accompanied by a pronounced olfactory impression of disagreeable nature.

*Münchener medicinische Wochenschrift, October* 13, 1903.

**A Misadventure Attending the Use of the Electromotor in Operating.**—Grosskopff describes an accident occurring to him while draining the antrum with an electric drill. After entering the cavity he was about to enlarge the opening with a second larger drill when he received an electric shock of such violence as to throw his arm to one side with great force. The consequences, had the instrument been in use in the antrum, or about the mouth, can easily be imagined. Investigation showed that the insulation of the rheostat had become defective so that a short circuit took place through his body. To avoid such mishaps he advises periodical tests of the insulation of the motor, etc., and that both patient and operator be placed on some non-conducting body, such as a rubber or linoleum mat.

**The Effect of Alcohol on the Size of the Heart.**—Bickel's results confirm those of Moritz, who was not able to detect, by means of his orthodiagraphic method, the dilatation of the heart which Smith and Hofmann determined by the use of the phonendoscope. Bickel made his observations on dogs, in order to be able to control them by immediate autopsy. By taking a large number of tracings he obtained composite pictures of unquestionable accuracy, and then gave the animals large amounts of alcohol subcutaneously, or by the stomach. Another series of determinations made during the various stages of intoxication up to the animal's death, did not yield results differing in any respect from those obtained before the administration of the drug, and autopsy demonstrated the correctness of the tracings. He, therefore, concludes that alcohol does not modify the size of the heart.

**Hypæthesia in Appendicitis.**—Peiser publishes the results of tests of the cutaneous sensibility of the abdomen in eleven cases of appendicitis. Of this number nine showed clearly defined disturbances of sensibility; in one case the results were variable and in one no abnormality existed. In six cases hypæsthesia was noted, in two hyperæsthesia, and in one at first hypæsthesia later followed by hyperæsthesia. A large number of healthy individuals were examined as a control, with negative results. The area affected was usually about the size of the palm of the hand, with its center at McBurney's point, but the outlines were not constant. The author considers the number of his cases too small to permit any deductions, but suggests the following points for further study: In what proportion of cases does disturbance of sensibility exist, and how is it divided between hyper- and hypæsthesia? What do the cases exhibiting each of these conditions have in common? Is there a difference corresponding to extra- or intraperitoneal appendices, or to the presence or absence of pus? Does the number of previous attacks influence the state of sensibility, and how are the changes to be explained?

**Observations on Alimentary Albuminuria.**—Ascoli and Bonfanti report a series of investigations on the blood and urine of healthy and nephritic individuals to determine whether their previous conclusion that egg albumen in cases of alimentary and other albuminuria can be identified in the body fluids by specific precipitin reactions, also holds good for other forms of albumin. Inasmuch as test-tube digestion has been found to exercise an inhibitory effect on the formation of recognizable precipitins it was necessary first to determine whether the natural processes had the same action. Observations showed that peptic digestion in the living body has but slight effect on the precipitable bodies in albumins, so that their absorption is not interfered with to an appreciable degree. The albumin chosen for experiment was beef albumin, and the blood and urine of sixteen persons were examined after they had taken one hundred grams of roasted beef the first thing in the morning. Two sorts of immune sera were used, both obtained from rabbits, in the one case after treatment with human serum, in the other after treatment with beef serum. The results of the study of the blood of the subjects after the ingestion of the beef may be grouped in two classes. In some the serum did not previously react to beef immune serum; in these, during digestion, it may either remain inactive, or it may respond to the precipitins. In others the serum already was precipitable with beef immune serum; in these digestion caused the reaction either to become more active, remain unchanged, or even disappear entirely. The study of the urine showed that in healthy persons, even when kept in bed, the urine, which previously did not respond either to human immune serum or to beef immune serum, may, after ingestion of beef, respond to both, and sometimes albumen may even be recognized by chemical reagents (Jolle's). Frequently the urine of nephritics also becomes precipitable by beef-immune serum after a beef meal. In some instances the urine which, while fasting, reacted positively both with beef-immune serum and with Jolle's reagent, lost both properties after the ingestion of the beef.

*French and Italian Journals.*

**Uterine Infection from Constipation.**—Achille Capaldi instituted a series of researches on guinea-pigs, with the view of ascertaining whether the uterus could become infected from retention of fecal matter in the intestines. He proved that following prolonged intestinal stasis there was a migration of colon bacilli from the intestines to the peritoneum and the uterus. The blood remained sterile. The constipation which is so frequently present in pregnant women is of slow onset, and is, therefore, not analogous to the rapidly produced retention of the author's experiments. Yet the fact that the bacilli do emigrate to the uterus may account for some lesions of the endometrium which produce abortion. The latter occurs frequently in cases of obstinate constipation.—*Archivio di Ostetricia e Ginecologia, Anno X*, No. 8, 1903.

**Articular and Abarticular Tuberculosis.**—Charles Fernet states that tuberculosis gives rise to articular symptoms of an acute, subacute or chronic nature, which are in many details analogous to articular rheumatism. They have been described under the name of tuberculous rheumatism, tuberculous pseudo-rheumatism, etc. This is incorrect, because it seems to imply some relationship to rheumatism, which does not exist. It would therefore be better to speak of articular tuberculosis, just as one says pulmonary tubercusosis, peritoneal and meningeal tuberculosis, etc.—*Bulletin de l'Académie de Médécine*, October 6, 1903.

**The Disinfectant Value of Alcohol Vapor.**—Paolo Satta concludes that the vapor of alcohol has a decided disinfectant action, that it is rapid, and is non-injurious to tissues and hangings. It has no toxic action, and after a slight ventilation of a quarter of an hour to expel the fumes of alcohol which might produce a little headache, the rooms which have been disinfected can be at once occupied. Its odor is not unpleasant, it is not expensive, the apparatus to be used is within reach of every one. It might be used to advantage in the disinfection of railway carriages as well as rooms.—*La Rifornia Medica.* October 7, 1903.

**The Significance of the Coagulation of Albumose by Ether.**—As a result of his investigations, M. Piery concludes that the coagulation of albumose in the urine by ether occurs in certainly half the cases in normal subjects. Pathologically it is found in a great number of patients suffering from the greatest variety of diseases. The preliminary chemical treatment to which the urine has to be subjected in order to avoid error very decidedly favors coagulation in both normal and pathological conditions. The general conclusion is that the coagulation reaction can be counted on to separate albumose from the various fluids of the body but that clinically the value of the procedure remains to be determined.—*Lyon Médical*, October 11, 1903.

**The Surgical Treatment of Pulmonary Tuberculosis.**—A. Demmler holds that thoracoplasty, which has given such brilliant results in certain cases of pulmonary cavities, may be used with equal success in the treatment of stationary tuberculous caverns, without complications in the other lobes, in order to remove a cause of infection and of denutrition which opposes recovery. Unfortunately the cases so far operated on have not been observed for a sufficiently long time to allow of an opinion as to its value in the treatment of the tuberculous process itself. The author reports six cases, in all of which there was marked improvement in the general condition, and in the local condition so far as shown by cough and expectoration.—*Gazette des Hôpitaux*, October 13, 1903.

**Massage of the Intestines.**—M. Froussard gives full directions for abdominal massage adding the following general rules: (1) No matter how much force be used, the massage should never be painful. (2) Fatigue must not be caused, and therefore, the first treatments must be short, or interrupted by periods of rest. (3) The stimulus produced by the massage on the intestines must always be in proportion to the power of contraction of the organ. (4) The masseur must know the condition of the organ which he is treating. Mechanical apparatus is, therefore, useless. The masseur should be thoroughly acquainted with the topography of the abdomen, and used to palpation. (5) All massage should be in the direction of the natural fecal movements.—*La Tribune Médicale*, September 26, 1903.

*Stated Meeting, Held October 15, 1903.*

ANDREW H. SMITH, M.D., PRESIDENT.

**The Wesley M. Carpenter Lecture: "The Diagnosis of Fevers."**—Dr. JOHN S. THACHER was the lecturer. He said that some of these diseases had no constant characteristic symptoms. Most fevers were the result of infection, and most of the symptoms were of a toxic nature. Typhoid fever, malarial fever, acute miliary tuberculosis, and influenza in some of their varieties or stages came into this group. Malarial fever generally ran a fairly typical course, but this was often wanting, especially in the estivoautumnal variety. The lawlessness of influenza in its clinical picture only needed to be mentioned. When the infection was very mild, or ran a brief course, the attack might be entirely wanting in diagnostic features. That typhoid fever might run a brief and mild course had long been known. As we progressed in diagnostic skill the number of cases classified as "febricula" steadily diminished. It must be remembered that in syphilis a considerable fever might be present at a time when other evidences of the disease were not apt to be present. It was of various degrees and types, though commonly intermittent, and it might run for weeks. It had been mistaken for malaria, cerebrospinal meningitis, malignant endocarditis, miliary tuberculosis, recurrent fever, influenza, typhoid, and some other diseases. In cirrhosis of the liver there was sometimes a fever associated with jaundice, a condition which was apt to give rise to a number of errors in diagnosis. In his experience the diagnosis of malignant endocarditis often required the aid of a bacteriological examination. The fever associated with concealed abscesses was another source of confusion, and it was surprising what large abscesses of the liver, kidney, and other organs could exist in the human body and evade the efforts of skilled diagnosticians. In children many suppurations of the middle ear were overlooked. In such cases leucocyte counts often proved to be very helpful. We were learning much in these days of the different causes of joint inflammations associated with fever. A correct etiological diagnosis of dysentery had already saved some lives by indicating the appropriate serum treatment. Special difficulty was often encountered when fever developed after an operation or after delivery. Not infrequently supposed sepsis after an operation proved to be only malaria. Mixed infections would be riddles impossible of solution without our new microscopical and bacteriological tests. Infections with streptothrix, pyocyaneus and the colon group of bacilli, together with paratyphoid infection, belonged to this group.

**Bacteriological Examination of the Blood.**—The malarial germ and the spirillum of relapsing fever were easily found in fresh spreads of blood. Usually in bacterial blood examinations it was necessary to make cultures. This had been done frequently in late years by many observers. Whereas only a few years ago it was stated on high authority that the typhoid bacillus was rarely found in the blood, there were now observers who reported series of cases, in from 70 to 100 per cent. of which the typhoid bacillus was detected in the blood. The best method of obtaining the blood for cultures was from the median basilic vein at the bend of the elbow, using a sterile glass syringe for the purpose. The greater success from recent bacteriological examinations of blood was largely dependent upon the use of a larger quantity of blood and of the culture medium. The best results had usually been obtained from several flasks, each containing from 100 to 400 c.c. of bouillon and from 1 to 5 c.c. of blood. Splenic puncture was not much used in this country, because it was considered somewhat dangerous, and practically as good results could be secured by taking the blood from a vein in the manner described.

The difficulty of distinguishing and separating the typhoid bacilli from other bacteria was particularly great in connection with the examination of the fæces. In spite of all the work done in this direction, the difficulties were so great, and the proportion of successful results so small, that it could not compare with the examination of the blood.

These studies of the blood had brought to light an interesting group of cases in which the microbe occupied a position intermediate between the typhoid and the colon bacillus. This group had been given the name of paratyphoid. The bacillus differed from the typhoid bacillus in its growth upon potato, and it was not agglutinated by typhoid serum. The symptoms of the infection were the same as those of typhoid, including rose spots, enlargement of the spleen and intestinal hemorrhage. The disease, as a whole, was usually milder, and such autopsies as had been made showed, as a rule, no changes in Perer's patches.

The Bacillus coli communis was frequently found in the blood post-mortem or shortly before death. As it was always so abundant in the intestine, its presence elsewhere was naturally suspected to be accidental. Some years ago it was believed to have little, if any, pathogenic power, but it had been shown that in certain conditions, as in a strangulated loop of intestine, or when transported to the peritoneum, it may become virulent and be capable of doing much harm. It might assist other bacteria in doing damage, and had been thought to start the formation of gallstones.

In making blood cultures to detect the gonococcus it must be remembered that this germ does not grow readily on many of the ordinary culture media.

Infections with the bacillus pyocyaneus had been found frequently in connection with inflammations of the middle ear and the cavities about the nose. It was especially dangerous in young infants, and sometimes gained an entrance through the unhealed umbilicus. Before making a diagnosis of this form of infection it should be recalled that this microbe was comparatively harmless, and might be present accidentally in the blood, and play a part entirely secondary to some other bacterium that had eluded our search. Only when abundant and pure growths had been obtained more than once should a positive opinion be expressed as to the existence of this variety of infection.

**Rheumatism.**—There was still much discussion as to what was the real cause of rheumatism. A certain micrococcus had been isolated which had been found to be pathogenic in animals. It grew best in highly alkaline media, rapidly produced a considerable quantity of acid, and would grow in media in which streptococci had previously grown. The speaker said that many experiments had been made by him to discover the specific germ of rheumatism, but the results went rather to show that the organisms found were accidental contaminations.

**Syphilis.**—Evidence was accumulating which made it probable that the germ of syphilis had been isolated from the blood.

**Examination of Cerebrospinal Fluid.**—It was not a difficult matter to obtain the cerebrospinal fluid for examination, especially if it were in excess of the normal, and the prevailing belief was that the danger of this procedure was insignificant. The diplococcus intracellularis meningitidis, the tubercle bacillus and the pneumococcus had been found to be the chief agents in producing meningitis. Not only were the results of bacteriological examination of this fluid important, but also the pressure on this fluid and the general appearance of the fluid. A high lymphocite ratio in this fluid pointed rather strongly to a tubercular meningitis.

**The Widal Reaction.**—Without discussing the theory of this phenomenon, reference was made to the value of

this test. The general experience was that the Widal reaction, carried out with a proper technique and using a dilution of at least one to forty when positive was absolute proof of the presence of typhoid fever, but its absence did not by any means exclude typhoid. The percentage of positive Widal reactions in typhoid fever was between 94 and 100. These figures would, however, be materially changed if attempts to obtain the reaction early in the disease were included. One observer, who had applied this test in 334 cases, found it present in only 6 per cent. of the cases at the end of the first week, whereas it was obtained in 36 per cent. at the end of the second week, in 67 per cent. at the end of the third week, and in 92 per cent. on the thirtieth day. Certain experiments seemed to show that the Widal reaction could not be depended upon when jaundice was present. Apparently the agglutination test was of no clinical value whatever in tuberculosis.

**Ehrlich's Diazo Reaction.**—The exceptions to the proper working of this reaction were many, according to the experience of most observers it was present in miliary tuberculosis, typhoid fever and measles, in a great many cases of scarlet fever and in other forms of tuberculosis. It was found frequently quite early in typhoid. Billings found it more frequently present than the Widal reaction. This test seemed to be of some value in prognosis. If absent early, it was a good sign. In pneumonia it was said to be a bad prognostic sign. While there was some difference of opinion with regard to its prognostic value in tuberculosis, the weight of evidence was distinctly in favor of the view that its presence, and more particularly its continued presence, pointed to a distinctly bad prognosis. A continuous and strong reaction indicated a probably fatal termination within six months.

**Tuberculin Test.**—Whatever doubt there might be about the therapeutic value of the tuberculin test, there could be no doubt that it had been of assistance in diagnosis both in the human subject and in animals.

In conclusion, the lecturer said that the foregoing presentation gave one some conception of the many and important acquisitions to our knowledge of diagnosis. Often the physician might with advantage call upon the laboratory for assistance, not only for the good of the particular patient, but for those who came after.

## MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

*Twenty-ninth Annual Meeting, Held at Memphis, Tenn., October 7, 8, and 9, 1903.*

The general session of the first day was called to order by the Chairman of the Committee of Arrangements, Dr. John L. Jelks.

Prayer was offered by Rev. Hugh Spencer Williams.

Addresses of welcome in behalf of the State and in behalf of the City of Memphis were delivered by Senator E. W. Carmack, and William B. Henderson, City Attorney. The response was made by Dr. C. H. Hughes of St. Louis.

**President's Address.**—Dr. Edwin Walker, Evansville, Ind., delivered this address. He urged the necessity of careful, accurate observation and study of cases, and the correct diagnosis of each one as an indispensable requisite to advancement in the profession. Experience was valuable in proportion as it was founded on accurate observation. If physicians incorrectly diagnosed their cases, how could they draw correct conclusions from their observations and treatment? If their premises were faulty, so also must be their deductions. The average physician lost enough time by careless, slipshod methods to master any branch of medicine. A method suitable to the students in the laboratory or a clinician in a large hospital was not the one for the practitioner of the cross-roads. Each must fit his methods to his needs. The practitioner remote from large centers must evolve his own system. He must have help. If his practice was large, an assistant or competent nurse chould be obtained. It was his belief that in the near future the trained nurse would become, in fact, a clinical assistant, relieving the busy doctor of many details, as testing urine, stomach contents, and other minor manipulations. Even those who were so remote as to be denied these aids could generally find competent persons in the community who could be taught to relieve physicians of much of this drudgery. Physicians should learn to save time and apply it to the essentials, leaving the details to others.

**The Decision to Operate.**—This was the title of the Address in Surgery, delivered by Dr. Ap Morgan Cartledge of Louisville, Ky. The speaker said he would impress upon both physician and surgeon the eternal fitness of time and opportunity as they related to surgical operations. The first great responsibility in deciding that an operation should be performed rested with the physician, who was keenly alive to the alarm and perturbation his announcement would cause to both patient and friends. Therefore, he should be prepared to make such announcement with the greatest clearness and candor, mingled with as much encouragement and hope as the condition would justify. A note of warning was sounded against the too common practice of treating surgical operations as trivial affairs, free from danger and pain. It was an excellent practice to say to a patient or those entrusted with his welfare, "If I should operate on a hundred people afflicted as you are, 86 (or 98, as the case may be) would recover, and 14 (or 2) would die." They would fully understand such a statement, and while it might sound a little cold and unfeeling, it would usually give more comfort and reassurance in the end than the unfortunate and usual plan of saying, "Oh, there is no danger whatsoever!" In cancer of the uterus, if seen early, the surgeon should advise complete removal of the organ at once, yet promise very little as to return of the disease, for there was no chapter in the history of malignant disease as gloomy as this. The permanent cures were few, even when the operation was performed in the first stages of the disease. Cancer of the breast was more hopeful, but hopeless enough. In cancer of the maxillary bones he believed it was sound practice to advise operation in almost every case affecting the lower jaw, and to refuse operation in almost every case involving the superior maxilla. Cancer of the alimentary canal was slower of growth and extension than was generally supposed, and early operations promised much more than was usually accredited to them. This applied especially to the rectum and anus, wide excision by way of resection giving the happiest relief from an otherwise wretched death. Surgeons should be slow to decide upon operation in chronic brain troubles, such as suspected tumors. They should decide quickly, however, upon operation in cases of compression and infections within the cranial cavity. Time was of more importance in acute peritoneal infections than in lesions elsewhere in the body. The great danger to life from peritoneal infection was at the onset, during the first thirty hours. Very early operations in acute abdominal lesions of a suspected infectious nature were often truly preventive of a rapidly fatal issue. It was in such cases that the physician should exercise the boldest and best knowledge in the decision to operate. The happiest time to operate upon intestinal obstruction was when the physician suspected the patient had one of the organic forms of this condition.

**Relation of the Medical Department of the United States Army to the Profession.**—Major W. C. Borden, Surgeon U. S. Army, delivered an address on this subject. It might be said that members of the medical profession who entered the medical department of the army separated themselves from their brethren in the profession at large. This was in part true, in that their life-work lay along different lines. Their work was

more or less of a special character, and their interests were different from those of their brothers in civil life. Nevertheless, this was true in part only, and the relation of the medical department of the army to the profession at large was really a most intimate one. The medical department was recruited from the profession at large, and was in touch with all the great interests of the medical profession. Problems of national importance, affecting both the general profession and the army, had to be dealt with by them. Numerous instances were given. It was only by mutual assistance and support that the profession could attain its highest ends

MEDICAL SECTION.

**The Prevention of Heart Disease.**—This was the subject of the Address in Medicine, which was delivered by Dr. ROBERT H. BABCOCK of Chicago. He discussed in what manner the principles of prevention could be applied to various heart affections. The first step in this direction was the realization that most of the cardiac inflammations were of microbic origin. Not infrequently cases of acute endo- and pericarditis, especially in children, had their beginning in a sore throat or an acute tonsillitis. If such significance could be attached to tonsillar inflammation, it opened up a field in which to work for the prevention of cardiac inflammation. All chronically enlarged or diseased tonsils which were not removed served as atria of infection for pathogenic organisms of all kinds. The importance of healthy noses and throats in children could not be too strongly insisted upon. The speaker then mentioned syphilis and gonorrhœa, saying that these diseases sometimes attacked cardiac structures. Pneumonia, chorea, and scarlatina were sometimes accompanied or followed by acute or chronic endocardial mischief; influenza or diphtheria might attack the myocardium in an inflammatory way so as seriously to impair its integrity.

**Medical Organization.**—Dr. T. J. HAPPEL of Trenton, Tenn., in discussing this subject stated that when the American Medical Association had drawn into its folds the members of the medical profession who should legally belong to it, there would be no trouble to secure a department of public health, with an officer at its head as a member of the President's Cabinet; and reciprocity in medical licensure would no longer be an idle dream. Uniform medical laws could be passed in all the States of the Union, with only such variations as might be demanded by the constitutions or laws of the different States; and then all the requirements could be so nearly alike for license to practise medicine and the examinations made upon such an equal basis that a license issued in one State would be accepted in another without question.

Dr. J. N. MACCORMACK of Bowling Green, Ky., followed with a paper on the same subject, in which he said that it was only a question of time when every State medical society in the Union would adopt the plan of reorganization of the American Medical Association. The results thus far accomplished were very encouraging. Of 120,000 physicians in the United States, only 30,000, or 1 in 4, had ever been members of any kind of organization, either County, State, or National. Within the last two years, however, progress had been very rapid in many of the States. For instance, in Michigan the membership of the State society within one or two years had increased from 490 to almost 2,100 members. In Kentucky from three hundred and some odd up to nearly 1,600. A marked increase had been observed in the membership of other States.

**Hypodermic Use of Mercury in Syphilis.**—Dr. S. P. COLLINGS of Hot Springs, Ark., said that mercury was the only drug we had that was a specific in syphilis, that all others were adjuvants only, and included among these latter were the iodine compounds. He recommended a formula containing bichloride of mercury, sodium chloride, and an anæsthetic, the latter to render the operation painless.

**Specialism in Its Modern Significance.**—Dr. ALBERT B. HALE of Chicago said that specialism had changed from its earlier conditions when tradition sharply defined the work, because the surgeon the obstetrician, or the internist recognized that no real dividing line separated their activities. The young man of to-day was so well educated by his college and even by his post-graduate school work, that he was able to practise in many departments formerly exclusively held by specialists. But modern specialism meant time to devote to the delicate technique of diagnosis and of treatment.

**The Early Diagnosis of Mental Diseases.**—Dr. C B. BURR, of Flint, Mich., read a paper on this subject. The definition of insanity, "A prolonged departure from the individual's normal standard of thinking, feeling, and acting," would, he said, for working purposes ordinarily be found sufficient. A comprehensive definition would include mental defect of whatever cause and mental perturbation of whatever degree. Subjects discussed at some length were the distinction between confirmed inebriety and true insanity of alcoholic origin, the differential diagnosis of alcoholic pseudoparesis and paretic dementia, certain phases of hysteria, and the diagnostic difficulties pertaining to paranoia and recurrent mania.

**Therapeutic Value of Heat and Cold Applied to the Spinal Cord.**—Dr. W. FRANK GLENN of Nashville, Tenn., contributed a paper on this subject, in which he drew the following conclusions: (1) Nothing should ever be put into the stomach except such substances as form a component structure of the body. (2) If this rule were rigidly adhered to, there should be no digestive disturbances, and all would have normal blood. (3) Since the blood was the life, when the blood had its structural elements normal and every cell was receiving its proper supply, no more, no less, disease could not exist. (4) Since it was known that the amount of blood in any part was controlled by the action of the vasomotor centers of the spinal cord, and the sympathetic ganglia in close proximity to the cord when these centers were performing their functions properly, the blood circulation must be normal and no disease could exist. (5) When there existed any disease causing an increase of blood in the capillaries of an organ, the application of heat over the vasomotor centers presiding over that organ caused almost at once a normal flow of blood in them, and consequently a normal circulation in the organ affected. (6) When there existed any disease which lessened the normal amount of blood in any organ, then the application of ice over the vasomotor centers presiding over that organ would cause a normal amount of blood to flow to that organ, resulting at once in a normal circulation and a consequent subsidence of the disease.

**Brain Strain Dyspepsia.**—Dr. C. H. HUGHES of St. Louis, Mo., called attention to conditions that were altogether too much overlooked in dyspepsia, as encountered among the brain strain and brain weary and worn men and women of affairs, connected with defective innervation in the stomach. A study of the pneumogastric nerve in its relation to the stomach, as well as to the remainder of the intestinal tract and the abdominal and thoracic viscera, with reference to the important origin and functions of the vagus nerve, and due therapeutic attention to these important relations gave physicians a broader and better plan of treatment, one that might always prove successful. He said we should seldom fail to cure dyspepsia, except when it arose from exceptional mechanical or chemical damage to the stomach. The treatment of the usually encountered dyspepsia was not complete with lavage, hydrochloric acid, pepsins, and pancreatins alone. The neural relations must be strengthened by treating the patient neurotherapeutically, and with especial reference to brain rest and restoration, for

dyspepsia was a disease of brain strain origin and defective vagus gastroduodenal innervation.

**What a General Practitioner Should Do in the Early Stages of Mental Disease.**—In a paper with this title Dr. BROOKS F. BEEBE of Cincinnati, Ohio, said that in the treatment of mental diseases the intelligent physician should proceed in the same way as in treating other affections. First, the cause should be removed, if possible. A great step in prevention was the proper rearing and education of children, for insanity was appearing at an earlier age than formerly. Few diseases were more susceptible to cure in the early stages than mental diseases. As a rule, it was not best for the patient to remain at home. Many owed their lifelong affliction to the ignorant sympathies of those dearest to them. Yet it was very doubtful if these patients should be subjected to the exhaustion of a journey. They should be closely watched, on account of suicidal impulse. Medication must be constructive and symptomatic. There were no specifics. Feeding was of great importance.

**Masked Epilepsy.**—Dr. W. B. FLETCHER of Indianapolis, Ind., said that this disease was usually unrecognized until it had progressed to a degree dangerous alike to the patient and those about him. Little was known of the pathology. Among adults it was usually caused by alcoholic, syphilitic, and autotoxic conditions. Treatment should begin with the mildest symptom, and war be waged on the vicious constitutional tendencies. During an attack hyoscin hydrobromate in $\frac{1}{70}$ grain doses every half hour induced quietude. The adult sufferer was a dangerous character, and all the crimes in the calendar might be committed by him unwittingly, and an afflicted innocent might be punished for a crime of which he was in no wise guilty.

**Nature and Treatment of Infantile Paralysis.**—Dr. ALBERT E. STERNE of Indianapolis, Ind., read a paper with this title. He said it was essentially an infectious disease, and was regarded by some authors as the purest form of a true nerve tissue process. Unless epidemic, diagnosis was almost impossible before there was evidence of spinal involvement. When the child first became ill, almost all symptoms pointed to an affection of the stomach, usually a couple of days before paralysis set in. If evidences of profound nervous involvement were found associated with vomiting, it should serve as a diagnostic and prognostic warning. There was not the slightest ground to fear that too active measures might be employed. Delay was inexcusable. Practitioners were confronted with a problem of a deep-seated inflammation in the spinal cord itself, a region not easy to reach. Counterirritation should be used along the spine; antiphlogistic applications should be made, and dry cold should be applied constantly to the vertebral column. Perfect rest must be maintained. No specific was known to the profession. After paralysis had set in, the nerve cells themselves were the seat of the inflammation. As soon as possible, electric stimulation should be applied to the paralyzed members.

**Action and Therapeutical Value of Currents of High Potential and Frequency.**—Dr. CURRAN POPE of Louisville, Ky., stated that too frequently the mind associated danger with the question of voltage, but voltage without amperage produced a current freed from all such danger. The current induced in the secondary coil was one of great current alteration. The primary sources of energy from which the high-frequency current might be obtained were the static machine, the induction coil, the commercial alternating current, and the Tesla coil. Special electrodes had been designed for the administration of the current. The application was painless provided the tissues covering the bony structures were not too thin. The physiological action was productive of excellent results; though painless, however, it might not be harmless for it might destroy the life of small animals. Its influence over the circulation was marked and produced intense vascularization of the skin. In a case of neurasthenia an abscess developed in the left thumb. The pus was evacuated and a high-frequency current applied for five minutes. Pain was immediately relieved, and no pus was found afterward. In another case with symptoms of formation of bone felon prevention resulted. These experiences had been repeated in many cases. The author was satisfied that the high-frequency current had a germicidal effect upon pus-forming bacteria, and that this was in proportion to the presence of the ultraviolet ray.

**Local Lesions and Treatment of Amœbic Dysentery.**—Dr. JAMES P. TUTTLE of New York City said that amœbic dysentery was ordinarily considered a tropical disease, but it was not unknown in its acute form in the United States. In its chronic form it was very common in returning soldiers. In all acute cases the subjective symptoms were the same as in sporadic dysentery, but the onslaught was not so sudden and tenesmus was less. Over 200 cases had been reported during the past year. It is stated by Lambert that he had found the bacillus in many cases of so-called chronic diarrhœa in children. There could no longer be any doubt that there was a type of dysentery due to infection by the amœba dysenteriæ. Whether catarrhal, bacillary or amœbic, dysentery had its origin in the large intestine. In his investigations the speaker had found that the ulcerative lesions decreased as we ascended upward from the rectum into the sigmoid, and in several instances entirely disappeared at the length of the sigmoidoscope. The disease appeared to have its beginning in the rectum and lower colon, judging from local examinations in acute cases. Ulceration of the rectum was always present in cases of chronic dysentery in soldiers returning from the Philippines. Complications might be summed up in abscess of the liver and stricture of the bowel. The *modus operandi* of the old-fashioned treatment of salts and soda was watery flushing of the canal, carrying the pathogenic organisms out of the body. Good reports had been obtained by colon flushing with solutions of quinine, but medicated solutions did not penetrate the tissues and reach the buried organisms. Experiments had shown that whenever stools were allowed to get cold, the life of the organism became extinct. This suggested the experiment of flushing the bowel with cold water, and repeated experiments had proved its worth. Flushings were given three or four times a day from a fountain syringe. In winter water direct from a hydrant was used; in summer a little ice was introduced. At least one douche a day was continued for eight weeks. A summary of the author's experience was as follows: Total cases treated, 63; cured, 61; disappeared, 1; abscess of liver, 1; died, none.

**Neuroses of the Stomach and Intestines.**—Dr. FRANK P. NORBURY of Jacksonville, Ill., said that, in reviewing the principal neuroses of the stomach and intestines, it was evident that the background of all, so far as causation was concerned, was the neuropathic constitution. A study of the extensive literature on the subject impressed one with the fact that in treatment one must first consider this basis, and while doubtless, as investigations went on in the study of these diseases, a more definite pathology would be outlined, and, as Riegel says, "many diseases we consider nervous to-day will in time be found to be based on pathologicoanatomical changes," yet one would always have to consider the predisposition as a primary and important etiological factor. In treatment it was necessary to follow the methods which best combat this feature, and which best subserve the observation of the case and the carrying-out of the details of treatment. The rest treatment met these indications, and how well depended upon the thoroughness with which it was practised. Rest in bed was most important. It was easier to institute this

treatment away from home, and in serious cases it was most important that the patient be isolated from friends and relations. Inasmuch as diet was one of the principal questions to be considered, it must be investigated thoroughly. Massage was considered next as an adjunct to treatment, essential in building up the wasted condition of the patient, and in arresting perverted metabolism. Electricity was the feature of treatment which gastrologists had developed in a special way. The medicines to be used were to be determined after a study of the chemical conditions of the stomach, and the rule should be to give medicines only when indicated. The special disturbances incidental to the neurasthenic state, namely, insomnia and constipation, were to be treated carefully and judiciously.

**The Principles of Diagnosis of Medical Malingering.**—Dr. JOHN PUNTON of Kansas City, Mo., discussed this subject in a paper, which will be published in the MEDICAL RECORD.

**Castor Oil in the Treatment of Typhoid Fever.**—Dr. C. C. BASS of Columbia, Miss., reported last year thirty-two cases of typhoid fever treated with castor oil. This year he reported forty-seven additional cases, which he and his associate had treated in the same way.

**Infantile Spinal Paralysis.**—Dr. ALEXANDER C. WIENER of Chicago said that infantile paralysis improved spontaneously in the first four months after the attack. From the establishment of the paralysis up to nine months the use of electricity, baths, massage, and gymnastics was indicated. It inhibited the fatty degeneration of those muscles which were only slightly damaged and which by judicious stimulation usually recovered their tone. After nine months had elapsed any therapeutic attempt was necessarily futile. Good functional results were obtained by a brace which would put the paretic muscles of the leg at an advantage over the stronger opponents. The permanent restoration of the balance of two opposing muscle groups might be effected in two ways. First, by implantation of the paralyzed tendon into a normal one of similar function. This method was called the ascending or passive tendon grafting, as used by Goldthwaite. Second, splitting off a part of the belly of a healthy muscle with its tendon and connecting it with the tendon of a useless muscle. This method created two new muscular individuals, so to speak, and therefore was called the active or descending tendon grafting.

**Leukæmia.**—Dr. WM. BRITT BURNS of Memphis, Tenn., read a paper on this subject, and exhibited a patient. He discussed the two recognized varieties of the disease; also the etiology, morbid anatomy, and treatment. His aim was to show the certainty with which one with the proper technique might make the diagnosis of leukæmia.

**Syphilitic Manifestations in the Nose and Pharynx.**—Dr. PAUL TURNER VAUGHAN of Hot Springs, Ark., stated that in looking over the clinical histories of five hundred cases of nose and throat syphilis, he did not find a single instance in which the primary sore was situated in either of these localities. Erythema, mucous patches, ulcerations, and gummata might at various times be found in the nose of the syphilitic patient. Mucous patches and ulcerations were present in the vast majority of those affected with syphilis during some stage of the disease. Primary sores of the pharynx were not met with in Hot Springs as often as one would suppose, judging from the material that had come under his observation, for among his cases of nose and throat syphilis he only found four cases in which the sore was situated in the pharynx. The initial sore when found in the pharynx usually lasted from four to six weeks, and did not differ materially from the primary syphilitic sore occurring in any other part of the body. The pharyngeal manifestations of syphilis in its secondary stage were the same as those present in the nose during this stage—erythema, mucous patches, and superficial ulcerative conditions

**Cyclical Albuminuria.**—Dr. ARTHUR R. ELLIOTT of Chicago presented a paper on this subject, which will appear in the MEDICAL RECORD.

**Chronic Interstitial Nephritis.**—Dr. R. ALEXANDER BATE of Louisville, Ky., defined this disease, and referred to the anatomical changes occurring in the different forms of nephritis. The prognosis was favorable in direct proportion to the earliness of the diagnosis. Nephritic changes were the result primarily of altered circulation. The changes in the epithelium of the tubules were secondary to those in the arterioles. Death finally resulted because the epithelial cells failed to excrete toxic principles, more or less normally secreted within the system, and habitually eliminated by the kidneys. The changes which occurred in the vascular system were alluded to. In the many cases now reported in which cures resulted from surgical operations upon kidneys which were the seat of chronic interstitial changes, the author thought that probably the stage of cardiac and arterial hypertrophy had not been reached. Certainly few tubular changes had occurred.

**The Use and Abuse of Fresh Air and Over-feeding in Tuberculosis.**—Dr. W. H. PRIOLEAU of Asheville, N. C., said it was no longer a disputed point that the treatment which offered most to the patient with pulmonary tuberculosis was a combination of the hygienic and dietetic methods. The proper feeding of the patient was equally as important as fresh air in the treatment of tuberculosis. One was dependent upon the other, and the two working together effected a cure more often than any other plan of treatment. It was in the nourishing of patients that most practitioners erred. They were not sufficiently careful in telling patients what they might eat and how much they must eat; or else, without due regard to the digestive and assimilative powers of patients, they ordered a full tuberculosis diet, and insisted upon its disposal in twenty-four hours. Ordinarily the digestive powers of the consumptive were poor, and if the stomach was overburdened and consequently upset, the sheet anchor was lost. The most injurious of all foods for consumptives were the starches.

SURGICAL SECTION.

**Why the General Practitioner Should Understand the Technique of Mirror Sight, with a Few Suggestions How to Learn It.**—Dr. ALLEN DE VILBISS of Toledo, Ohio, said there were general practitioners who did not understand how to handle a laryngeal or rhinoscopic mirror, and he regretted to say that some nose and throat specialists did not understand the technique of mirror sight. Examination of the nose, nasopharnyx, and larynx was made by reflected light, as only the mouth and vestibule of the nose could be examined without it. To do this, all that was actually needed was a concave mirror, tongue depressor, nasal speculum, two different sized rhinoscopic and one laryngeal mirror.

**Principles in the Treatment of Chronic Otitis Media Purulenta.**—Dr. JOHN F. BARNHILL of Indianapolis, Ind., said a study of sections of the temporal bone, made through various parts of the middle ear and its neighboring connected cavities, would give the physician a necessary and wide opinion of the extent and importance of the hearing organ as a whole, which was too often ignored as trivial. Such study would teach (1) that the cavity of the middle ear was not and should not be regarded either as an anatomical or pathological entity, but that it was only a highly important division of the chain of cavities which comprised the conducting portion of the hearing apparatus, all of which cavities were directly connected and lined by mucous membrane. (2) That extension of disease from one cavity to another must not only be considered as a possibility, but more as a probability, either through contiguity of tissue or by the migration of pus-bearing fluids. (3) That the cavity of the middle ear was the only portion of the extensive irregular tract that was directly accessible to the view of the operator and to instrumentation. There-

fore, when disease existed in the mastoid antrum, or the maze of the cells beyond it, the same could not be reached through the external meatus and middle ear. (4) That both the antrum and middle ear were separated from the cranial cavity by only a very thin osseous partition, and that therefore fluid spent up within these cavities were as likely to rupture into the cranium as upon its surface.

**Nasopharyngeal Adenoids.**—Dr. J. A. STUCKY of Lexington, Ky., in discussing this subject drew the following conclusions: The obstructive and non-obstructive adenoid tissue, when diseased, was a menace to health, hearing, mental and physical development, and should be radically dealt with. It was far more serious in its effects than disease and enlargement of the faucial tonsils. Frequently when the pharyngeal tonsil was thoroughly removed, the enlarged faucial tonsils rapidly assumed normal size and function. While this was not the rule, he had seen it occur so frequently that it was safe to say that it was far more than the exception to the rule. The technique of adenectomy was simple, as compared with many other surgical operations, but should be just as conscientiously carried out. When carefully and thoroughly done, the results obtained were only equaled by some of the so-called major operations performed by the general surgeon.

**Penetrating and Perforating Gunshot and Stab Wounds of the Abdomen.**—Dr. JOHN YOUNG BROWN of St. Louis, Mo., in a paper on this subject, discussed the preparation of the patient, search for visceral injuries, control of hemorrhage, irrigation and drainage, closure of incision, and then reported nine cases of perforating wounds of the intestines, with six recoveries and three deaths. One death was due to shock. In this case the injury was so extensive that the patient never reacted. The second patient entered the hospital with general peritonitis, and while a perforation was overlooked it was probable that the result would have been the same if the injury had been repaired. The third patient he thought should have been saved. Of wounds of the liver, five cases in all, four patients recovered and one died. This one died three hours after operation from shock, which was the result of hemorrhage. The patient with wound of the pancreas recovered. To these cases he added eight in which laparotomy was performed and no injury to the viscera found. This made a total of 23 cases, with 19 recoveries and 4 deaths.

**Surgery of the Thyroid.**—This was the title of an exhaustive paper by Dr. B. MERRILL RICKETTS of Cincinnati, Ohio, in which he drew the following conclusions: (1) The thyroid is oftener abnormal than normal in size, shape, number of lobes, and accessory lobes more frequently on the left side. (2) The physiological function of the thyroid and its secretions and relation to other glands are not understood. (3) There may be but one lobe. It may be situated anywhere in the anterior, lateral, or posterior portion of the neck, or it may be intrathoracic, subclavicular, or postscapular. (4) It is the most constant of all the glands in animal life, and all vertebrates are subject to the same laws concerning it. (5) Absence of the thyroid at birth results in cretinism, and its destruction by disease, or otherwise, in adult life induces myxœdema. (6) Parenchymatous goiter, cause not known. (7) May develop in fetal, infant, child, or adult life. (8) All animal life is subject to it. Cause of exophthalmic goiter unknown. (9) Patient may or may not have protrusion of eyeball. (10) Lesions of restiform body in rabbits and dogs, and probably all other animals will induce exophthalmos and tachycardia, also tremor, polyuria, glycosuria, and salivation. (11) Medicaments are of no avail except to palliate. None cured. Animal extracts most satisfactory for palliation. Surgery offers the only means of relief. (12) Thyroidectomy is the operation of choice, is done more quickly, with less mortality, and better results. (13) Concretions may be osseous or calcareous. (14) Cysts should be removed by thyroidectomy, whether they contain blood serum, or pus of parasitic, benign or malignant origin. (15) Gangrenous and tubercular thyroid tissue should be freely excised. (16) Syphilitic gummata may be congenital or acquired, and should be subjected to syphilitic remedies to which they will yield. (17) Transplanted segments of thyroid tissue will, more or less, contain life. (18) Electricity in any shape is not only useless, but very detrimental, in that it causes the formation of adhesions, which greatly interfere with subsequent surgical operations. (19) The use of the seton, and incision into the thyroid are seldom indicated, except for the removal of concretions or foreign bodies. (20) Injections of crystals, solutions, or cautery of any kind should not be tolerated. Like local applications of any character, they should be condemned, and relegated. (21) Division or resection of the thyroid isthmus does not cure. It has no place in thyroid surgery, and should become obsolete. (22) Partial thyroidectomy is the proper term, as the entire gland is seldom removed. (23) Chloroform, local anæsthesia, and the use of cocaine for local anæsthesia are the most desirable. (24) The mortality is less than one per cent. in the general application of thyroidectomy. It is the operation of choice. (25) All thyroid tissue should not be removed unless malignant. (26) Regeneration of thyroid tissue, that will secrete thyroidin, is just as impossible as the regeneration of a finger. (27) Death from hemorrhage in thyroidectomy need not occur, as blood vessels of any size or in any location may be closed by ligature or forceps. (28) Litigation of the thyroid arteries is ineffectual and obsolete. (29) Compression of goitre sufficient to be beneficial would occlude the trachea and larger blood vessels of the neck. (30) Tracheotomy is indicated when the goiter presses upon the trachea, or blood vessels, producing alarming effects, and then it should be done only to palliate until thyroidectomy can be performed.

**Extrauterine Pregnancy.**—Dr. A. H. CORDIER of Kansas City, Mo., discussed the pathology, diagnosis, and treatment of this condition. In ten years he had had an experience of forty-four cases. Intraperitoneal was to extraperitoneal rupture in the proportion of three to one. When rupture took place between the layers of the broad ligament, the hemorrhage was limited by the resistance offered by the surrounding structures, death rarely occurring to the patient from the first rupture. The tubal mucous membrane played a very trifling part in the formation of the placenta in ectopic gestation. The placenta in these cases was derived almost entirely from the fetal structures. The diagnosis of ectopic pregnancy prior to rupture was attended with great difficulty and was rarely made. In many of these cases there was a history of some menstrual irregularity or deviation from the accustomed course in the case under investigation, such as the missing of one or two periods, or an irregular intermenstrual period or flow occurring in a woman previously regular, culminating in an attack of acute suffering in the region of either uterine appendage, accompanied by shock and symptoms of lost blood. The question of treatment of these cases was so thoroughly settled as to admit of very little discussion. The technique of individual operations varied according to the indications to be met in the midst of the operation. The operation of choice was a median suprapubic section, with removal of diseased structures. Vault drainage in ectopic gestation was an incomplete procedure, attended with much danger at the time of the operation, leaving the woman with a pathology that would in most instances continue to produce disagreeable or dangerous symptoms until it was completely removed.

**Ectopic Gestation.**—Dr. ANDERSON WATKINS of Little Rock, Ark., reported a case with complications. The points of interest were (1) the typical history; a long

period of sterility succeeding a normal pregnancy; the absence of menstruation for four months; enlargement of the breasts; morning sickness; shedding of the decidua, and finally a feeling on the part of the patient as though she were pregnant. (2) The evident repeated ruptures of small extent, followed by sepsis. (3) The impropriety of waiting a week after diagnosis to operate. (4) The use of drainage and irrigation. (5) The complicating nephritis, probably of toxic origin. (6) The intercurrent malarial infection during convalescence, and also the intestinal disturbances, which were a constant drawback to improvement. (7) The location of the pregnancy, primarily tubal, although much disguised after rupture and the exudation of plastic lymph.

**The Causes of Occasional Failure of Operation to Cure Gallstone Disease.**—Dr. Wm. J. Mayo of Rochester, Minn., said with a single exception, to which he referred later, all of the cases in which results were less perfect than were desirable were complicated cases, and it could be laid down as an axiom that delay in seeking surgical relief was the direct cause of the complication. It was the general experience that complicated cases had usually had symptoms during a period sufficiently long to have made a diagnosis possible before the development of serious lesions, and that an operation at that time would have been safer and the cure more certain. He referred to the clinical fact that a small number of patients who had had a cholecystostomy performed would have a colic or two following operation, and sometimes accompanied by transient jaundice. He had seen this most frequently during the first month or two after the patient was discharged from the hospital. The most common cause of future symptoms was incomplete removal of stones. Stones in the cystic duct frequently escaped attention, and it was only after several such misfortunes that he began to exercise greater care in exploring this canal. The parts were deeply situated, and as these patients were often obese, it was not easy to locate such a calculus previous to the development of the Robson technique. In most of the cases of stone impacted in the cystic duct, cholecystectomy was indicated. One source of failure of cholecystostomy to cure was secondary obstruction of the cystic duct, preventing free drainage of the gall-bladder down through the passages. This might eventuate in a mucous fistula or repeated attacks of colic, as the gall-bladder secretions were periodically forced through the strictured canal. In septic cases, drainage was necessary for a long period of time, and if the fistula was allowed to close too quickly, severe symptoms might ensue. He had twice had to reopen and re-establish drainage in septic cholecystitis. Both cases were colon infections. Stones were often overlooked in the common duct, as they might lie quiescent for years. The jaundice might be very slight, and in some cases not noticeable. The gall-bladder in the meantime might become obstructed at the cystic duct, so that this organ might be enlarged and cystic, with calculus at the neck and nothing to call attention to the common duct stone. Chronic pancreatitis might exist at the time of operation and to obtain a good result drainage must be long-continued. Cancer could also be said to be secondary to stone formation, and might take place after cholecystostomy or, being present, might be mistaken for inflammatory disease. All thick-walled gall-bladders should be looked upon as suspicious, and as they were functionally useless, cholecystectomy should be done rather than cholecystostomy, and in this way many early cancers would be found and cured. Persistent biliary fistula usually meant obstruction of the common duct. Everyone understood the importance of not attaching the gall-bladder to the skin. In the early days persistent biliary fistula was usually due to a mucocutaneous suture. This practice was now obsolete. The turning-in of the margins of the incision of the gall-bladder, and drawing a purse-string suture closely about the drainage tube in a similar manner to a Kader gastrostomy, enabled healing of the fistula to take place most promptly after removing the drain. Secondary operations had been comparatively safe in his experience. The patient had become accustomed to the condition, and the adhesions formed a protective barrier. Separation of the adhesions, particularly about the liver, resulted in considerable hemorrhage. Rather prolonged gauze pressure usually checked the oozing, as the blood pressure in the liver was very low, and enabled completion of the operation. Most of the cases required a light gauze drain protected by gutta percha tissue at points of contact with the stomach or intestine, to prevent troublesome adhesion to the gauze. Deep drains should be anchored with catgut to prevent displacement by movements of the liver, as affected by the diaphragm. The catgut became absorbed before the time for withdrawal. The drains should not be removed too early, six to twelve days being the usual limit as to the time of withdrawal.

**Diagnosis and Operative Treatment of Gallstones.**—Dr. W. D. Haggard of Nashville read his paper. The most valuable local sign was hypersensitiveness under the tip of the ninth costal cartilage. A distinct tumor was not often felt, and was therefore not diagnostic of gallstones. In long-standing cases of inflammation in and around the gall-bladder, an ill-defined tumor was present, but the tenderness precluded its exact definition. Hydrops from a stone in the cystic duct gave the typically enlarged gall-bladder, and empyema was also characterized by tumefaction. Stones in the gall-bladder without inflammatory or other complications were never attended by enlargement, and an enlarged gall-bladder meant there was no stone in the common duct, as enunciated by Courvoisier. This was a most valuable differential sign. In biliary obstruction manifested by chronic jaundice, an enlarged gall-bladder meant that the obstruction was not due to a stone. Jaundice following attacks of biliary colic was not necessarily due to calculous obstruction, but was usually caused by an inflammatory turgescence of the bile tracts that offered a certain resistance to the outflow of bile. The author reported a case which illustrated this point.

**The Prophylaxis of Tetanus.**—Dr. S. C. Stanton of Chicago contributed a statistical paper on this subject. He considered the prophylaxis under five heads: (1) The enforcement of existing laws regarding the sale of toy pistols and other dangerous toys; (2) the enactment of laws by Congress, State legislatures, and municipalities prohibiting the manufacture and sale of toy pistols, blank cartridges, dynamite canes and caps, cannon crackers, etc.; (3) the open treatment of all wounds, however insignificant, in which from the nature or surroundings there was any risk of tetanus; (4) the immediate use of tetanus antitoxin in all cases of Fourth of July wounds, wounds received in barnyards, gardens, or other places where the tetanus bacillus was likely to be present, or tetanus infection to occur; (5) the injection of tetanus antitoxin as soon as tetanic symptoms became manifest.

**Indications and Technique of Prostatectomy.**—Dr. G. Frank Lydston of Chicago, in a paper with this title, pointed out that the senile prostate was an atrophied prostate. Catheter life lasted for about five years, although Reginald Harrison had put it at four years. Operation should be performed immediately upon the discovery of prostatic enlargement, due deference being paid to inflammatory and congestive disturbances of the organ, which could be relieved in many instances without surgical treatment. In referring to the pathology of hypertrophied prostate, the author expressed the belief that it was glandular at the outset, the tumor being purely adenomatous. He exhibited several specimens of prostates which he had removed from time to time, and said that early operations on the prostate in otherwise healthy subjects were no more dangerous than

interval operations for appendicitis. The perineal operations should be performed whenever practicable, but the author was aware that there were cases which could not be dealt with successfully by this route; therefore, it might become necessary to resort to the suprapubic or the combined perineal and suprapubic operation.

**Surgery of Pulmonary Gangrene.**—Dr. L. L. McARTHUR of Chicago, after reporting three cases representing three varieties of gangrene, presented the following conclusions: (1) That since by medical treatment 80 per cent. die, and in those operated about 29 per cent., efforts should be surgical. (2) That while it was anatomically possible to separate the pleura from the chest wall, it was tedious, difficult, and often futile (due to puncture), and therefore not much valuable time should be lost in such efforts. (3) That circular suture combined with gauze pressure packing for forty-eight hours was the best means of inducing adhesions. (4) The *x*-ray might give valuable aid in localization. (5) Great care should be used in the selection of cases for operation, but when localized and single, the most desperate cases should be given a change, as they frequently recovered with drainage.

**The Present Status of Stomach Surgery.**—Dr. A. J. OCHSNER of Chicago said that in the diagnosis of surgical diseases of the stomach great difficulty was occasionally found in eliminating cases suffering from gastric disturbances due to general neurasthenia, because the latter condition was frequently the result of gastric disease which could be relieved by surgical means. Among the conditions which simulated stomach disease, gallstones undoubtedly stood first in point of frequency, and not infrequently the adhesions accompanying the presence of gallstones resulted in a distortion of the pylorus, which virtually caused an obstruction. One condition which the surgeon encountered occasionally was locomotor ataxia with marked pain in the region of the stomach. This condition was easily detected during a careful examination, but it had occasionally been overlooked. Of all the operations employed in stomach surgery, gastroenterostomy was the most commonly indicated, because it supplied drainage of the organ, and as the want of this drainage was the cause of most of the surgical diseases of the stomach, its accomplishment must necessarily be of the greatest importance. Pyloroplasty was still under observation. Mikulicz, Finney, and a few other surgeons had spoken well of the operation in selected cases of cicatricial constriction of the pylorus. The author's own experience had not been satisfactory with this operation. The method introduced by Finney was undoubtedly the best. The results of pylorectomy would undoubtedly be more and more satisfactory, because these patients were likely to come to the surgeon before the carcinoma had advanced to the hopeless condition usually encountered at the present time. The results of Mikulicz, Kocher, Czerny, and a few others were even at the present time sufficiently satisfactory to warrant the operation. Gastrectomy was indicated in only a very small number of uusual cases. Gastrostomy was indicated in all cases of obstruction of the esophagus due to carcinoma in which starvation was imminent. The patient received a great amount of comfort from this operation. As to gastroduplication, this operation would hardly again receive any prominence, because the same end could be obtained so much more certainly, safely and easily by making a gastroenterostomy.

**Treatment of Tuberculous Joints.**—Dr. DAVID C. PEYTON of Jeffersonville, Ind., said the surgical treatment of tuberculous joints presented for consideration the following operative procedures, according to the state of advancement of the joint involvement: Arthrotomy, arthrectomy, excision or resection, and amputation. By the early and free opening of the affected joint, thus insuring free drainage, and thoroughly irrigating it with a hot saline solution, the writer had obtained very satisfactory results. The irrigation should be repeated daily for a week or ten days, or even longer, according to the degree of involvement. Even when the process had proceeded to suppuration or beginning necrosis, one might expect most marked benefit from this plan of treatment, and which was especially to be commended in all patients under eighteen years of age, for by the more radical operations the surgeon might destroy the epiphyses, with consequent arrest of development or growth. However, in the advanced state of the disease, whether in the adult or the child, the more radical operations were not only advisable, but were imperatively demanded to save usefulness of limb, and sometimes life. When fistulæ had formed, their removal by arthrectomy or excision was insisted upon. It was especially in the smaller joints that the most satisfactory results were obtained by arthrotomy and arthrectomy.

**Treatment of Compound Fractures, Immediate and Remote.**—Dr. FREDERIC A. BESLEY of Chicago discussed the causes of these fractures, and the pathological conditions met with. He divided the treatment into the (1) primary treatment of the wound; (2) the application of an immobilizing dressing; (3) subsequent dressings of wound; (4) methods of procedure in the event of suppuration; (5) treatment of non-union of the fragments. These several divisions were taken up and discussed at length.

**The X-ray in Fractures.**—Dr. DUNCAN EVE of Nashville, Tenn., said that at present the *x*-rays were of more assistance in the investigation of the pathology of fractures than in the treatment and the more precise the knowledge of the pathology, the more satisfactory the treatment. The exact diagnosis of fractures of certain bones without an *x*-ray examination was always open to doubt. In order to secure the best results from the Röntgen rays, not only must the apparatus be good, but the man who uses it must have experience. Skiagrams produced by a beginner lacked clearness, and might lead to erroneous conclusions. He concluded by quoting from a well-known *x*-ray authority, who had said that "when the limits of error are kept clearly in mind, the actual value of the discovery of Röntgen to surgical science is immense. When there is doubt of the diagnosis of a fracture, no physician has done his full duty by his patient if he can command skiagraphic examination and has not used it."

**Officers.**—The following officers were elected for the ensuing year: *President*, Dr. Hugh T. Patrick of Chicago, Ill.; *First Vice-President*, Dr. Bransford Lewis of St. Louis, Mo.; *Second Vice-President*, Dr. Geo. W. Cale of Springfield, Mo.; *Secretary*, Dr. Henry Enos Tuley of Louisville, Ky.; *Treasurer*, Dr. Thomas Hunt Stucky of Louisville, Ky. The time and place for holding the next annual meeting were left to the president, secretary, and treasurer to decide.

---

**Rheumatic Perichondritis of the Left Ear.**—I. Valentine Levi reports the case of a boy of ten years, whose history, physical signs, and symptoms led to a diagnosis of articular rheumatism. The peculiarity of the case consisted in the involvement of the left ear, which showed little alteration in conformation except disproportionate thickening, but which was greatly increased in size as compared with the right ear. The longest vertical diameter was 7 cm. as compared to 5.5 cm. in the right; the greatest horizontal diameter 5.5 as compared to 4.5 cm; from the tip of the tragus to the periphery, on a horizontal line, the left measured 4 cm. and the right 3 cm. This involvement of the ear occurred during an attack of acute articular rheumatism, and must be ascribed to the same agency that caused the other rheumatic symptoms.—*International Medical Magazine.*

## CONFERENCE OF STATE AND PROVINCIAL BOARDS OF HEALTH OF NORTH AMERICA.

*Eighteenth Annual Meeting, Held at Baltimore, Md., October 23 and 24, 1903.*

**Special Report to the Medical Record.**

THE Conference met in the hall of the Medical and Chirurgical Faculty of Maryland, and was called to order by the First Vice-President, Dr. John Guitéras of Havana, Cuba, in the absence of the president.

An address of welcome on behalf of the Faculty of the University of Maryland was delivered by Dr. JOHN F. CORDELL, who, in referring to the early medical history of Maryland, stated that the Medical and Chirurgical Faculty, organized in 1802, was the first body of the kind to give a formal endorsement to vaccination. As a matter of equal importance, he mentioned that papers were written in 1807 by John Crawford advocating and favoring the animalcular theory of disease. These papers were published in a non-medical journal, for the reason that the editor of no medical journal at that time would accept them. Crawford was erratic, but considered far ahead of his time. He was the first in any English-speaking country, so far as the speaker knew, to advocate the germ theory of disease. Crawford antedated Lister by at least fifty years, as a perusal of his writings would show this.

Dr. WM. H. WELCH of Baltimore followed with an address of welcome on behalf of the State Board of Health of Maryland. He said, among other things, there was another name which should be mentioned in connection with the medical history of Maryland that of John K. Mitchell, father of Weir Mitchell, whose book on the "Cryptogamic Origin of Malarial Fever" was really a classic. He thought Mitchell's name should be coupled with that of Henle, who forecast the doctrine of *contagium vivum*.

The First Vice-President responded briefly to these addresses of welcome.

**Etiology and Prevention of Infantile Diarrhœa.**—Dr. JOHN H. MASON KNOX of Baltimore read a paper on this subject. He said no single organism was considered to be the cause of infantile diarrhœa until the experimental work of Duval and Basset. Following Shiga's work in 1898 the dysentery bacillus was found to have wide distribution, and from year to year the distribution of the organism had been found to be more general. Reference was made to the investigations of Flexner in the Philippines in relation to dysentery among soldiers and the Shiga bacillus as a cause of it. Subsequent investigations made by bacteriologists in Germany, China, Constantinople, etc., disclosed the existence and prevalence of this bacillus in epidemic dysentery, so that its pathogenicity was now well established. At the suggestion of Flexner, the speaker and others undertook a series of investigations at the Wilson Sanitarium, and of fifty-three cases of diarrhœa carefully examined, the Shiga organism was found in greater or less number in forty-two. Careful clinical examination, however, showed definitely that no one type of the disease could be associated with this organism, and that intestinal diseases of all types, common among children in summer, were caused by the same organism. Laboratory investigation had shown two or three types of organism very closely related. Thus far the great majority of cases in babies had been the acid Harris type. It was found that not only during the summer, but in the winter, sporadic cases of infantile diarrhœa were associated with this organism. Wolfstein had reported thirty-seven sporadic cases of infantile diarrhœa occurring in winter, and Basset four cases, seen in the Johns Hopkins Dispensary, due to this organism. Shiga, by the serum treatment, had reduced the mortality of dysentery from 20 to 30 per cent. to 10 and even 7 per cent. In twenty-five cases treated by injections of serum at the Wilson Sanitarium, some betterment was noticed after the injection in the cases that were seen early, but the improvement was not brilliant or startling. In eight cases the serum had a beneficial action. In connection with the serum there were changes made in diet, and other medication was used, so that the results obtained were confusing in their interpretation. In cases of long standing, associated with an inflammatory condition of the intestinal tract, in which there was probably ulceration, blood in the stools, etc., the serum was of no avail. Although the serum treatment was not very beneficial, it was harmless, as no deleterious effect was observed in any of the cases.

**Are the Laboratory Methods of Diagnosis in Infantile Diarrhœa Applicable in Public Health Work?**—Mr. EDWIN G. SCHORER of Baltimore, in a paper on this subject, said that with the establishment of the etiology of infantile diarrhœa, a great step in advance had been made, yet under the present conditions the new methods of diagnosis were not practicable in public health work. This last statement might, however, be modified, inasmuch as a bacteriological diagnosis would undoubtedly be of value in the limited number of persistent cases of diarrhœa, and in those in which the antidysenteric serum was to be given. For this purpose the mailing case of Dr. Parks was to be recommended. The fact that, at the present time, the methods were not available for general diagnostic purposes, ought not to discourage any one from complying with any request boards of health might make. Much was still to be learned in regard to the dysentery organism and infantile diarrhœa, a good share of which could be furnished by statistics obtained and facts learned from local boards of health.

Dr. WILLIAM H. WELCH of Baltimore said it was a surprise to him that Dr. Knox had found the organism, which had been proven to be the cause of a prevalent group of cases of dysentery, to be the cause of summer diarrhœas of children as well. One did not think of the ordinary summer diarrhœa of children as belonging to the same group of cases as adult dysentery. The organism must be found in other localities than Maryland in order to demonstrate that it had any causal relation to infantile summer diarrhœa. The serum treatment of this disease, according to Flexner, was disappointing. The best results had been obtained in the treatment of adult dysenteries. Instances had been reported by Holt, Thayer, and others in private practice in which the serum seemed to have had a marvelous effect. Conditions in hospital and dispensary practice, however, were unfavorable for obtaining satisfactory results with serum.

Dr. HENRY M. BRACKEN of Minneapolis referred to the milk question, saying in the larger cities it was difficult to get a pure milk supply. What was generally known as certified milk was one of the best articles of artificial diet for children. At present much attention was being paid in some cities to securing a pure milk supply by excluding tuberculous cows from dairies. But even this would not insure a pure milk supply, by any means. The testing of dairy herds for tuberculosis might be satisfactory to the dairymen and seemingly protect the people, but there were more infants that died every year from impure milk than from tuberculous milk. More attention should be given to the sanitary aspects of the dairy than to the diseased animal. Certified milk and pasteurized milk were as satisfactory articles of diet as could be obtained at the present time.

Dr. JOHN N. HURTY of Indianapolis, Ind., cited an instance showing that typhoid fever and dysentery (epidemic) could be conveyed by flies as well as by polluted water.

Dr. CHARLES O. PROBST of Columbus, Ohio, considered it very important to disinfect the stools in cases of infantile diarrhœa, although Dr. Knox had not referred to it. He understood Dr. Knox to say that the Shiga bacillus inhabited the healthy intestinal canal, and that under certain

conditions of environment it might take on pathogenic properties. He asked whether this was so or not.

Dr. GARDNER T. SWARTS of Providence, R. I., understood that the Shiga organism was easily killed in the presence of other bacteria, as the colon bacillus, which was a common inhabitant of the intestinal canal. If the Shiga organism was so easily killed in the presence of other bacteria, why did it prevail so extensively?

Dr. S. R. TOWN of Omaha cited an epidemic of diarrhœa which occurred in Chicago many winters ago, which was caused apparently by the discharge of a large quantity of surface material into Lake Michigan.

Dr. JOHN N. HURTY cited a similar epidemic which occurred in Michigan City, Ind. There were no less than three thousand cases of diarrhœa from polluted water.

Dr. HENRY D. HOLTON of Brattleboro, Vt., thought that infantile diarrhœas were considered gastrointestinal diseases, and that dysentery simply applied to bloody flux, which was not common in infants, but was sometimes seen.

Mr. FRANK WELLS of Lansing, Mich., said the Michigan State Board of Health had published a leaflet on the subject of infantile diarrhœa as the result of a report made by Prof. Victor C. Vaughan. This leaflet, which had been given wide circulation, advised that all cow's milk given to infants shall be pasteurized. The leaflet was furnished to all of the teachers of public schools in Michigan. It was the duty of boards of health, he thought, to furnish such information to the people.

Dr. HENRY MITCHELL of Asbury Park, N. J., urged repeated inspections of cases of diarrhœa in children and adults, as in cases of typhoid fever. The New Jersey Legislature had given the State Board of Health authority to make such inspections. A law had also been enacted that no milk shall be sold from premises on which there was an impure water supply. He pointed out how this law could be so interpreted as not to be effectual in its administration.

Dr. Knox, in closing the discussion, emphasized the importance of good milk and pure water for children, as well as adults. Common house flies were carriers of disease; they were a source of contamination in many instances. Proofs of this were abundant. Replying to Dr. Probst, he said the disinfection of stools in cases of infantile diarrhœa was as essential as in typhoid fever. In speaking of dysentery he had not meant to confound it with bloody flux, as intimated by Dr. Holton. He used the term dysentery to include those cases in which the Shiga bacillus was found to be present. He could not answer satisfactorily the question of Dr. Probst relative to the Shiga organism inhabiting the healthy intestinal canal, but hoped Professor Welch would do so.

Dr. Welch said the Shiga organism was not present in normal stools. If it was, it was in such small numbers that it required the most painstaking investigation to find it.

Mr. Schorer cited an instance explaining why the colon bacillus killed the Shiga organism. The organism of dysentery was found in the mucous coat of the intestine, while the colon bacillus might be found in any part of fecal matter.

**The Duty of Sanitarians Regarding Venereal Diseases.**—Dr. HENRY D. HOLTON of Brattleboro, Vt., read a paper with this title. He emphasized the duty which should be recognized by sanitarians as resting upon them, of doing something to restrict the venereal diseases which threatened society as no other communicable diseases did. The vital statistics of New York City in 1900 had a record of 31,145 cases of contagious diseases, with 11,368 deaths, of which only 177 were from syphilis. Blascho claimed 150,000 syphilitics for Berlin, and the Committee of Fifteen, 200,000 for New York City. To get an approximate idea of its prevalence the Prussian Government requested that all physicians should report on August 30, 1900, every case of venereal disease coming under treatment. These reports proved that three-quarters of a million people were afflicted yearly with venereal diseases in that country alone. He said the foregoing statements would prove that venereal diseases stood next to in prevalence tuberculosis and alcoholism, if they did not surpass them. They were permeating the very root of the population, tainting those yet unborn, maiming those born with the virus already in their blood, deteriorating the race, and devitalizing the individual. Instruction should be given in high schools and colleges, having reference to the prevention of these diseases. Dr. Prieto, in a paper read at the International Medical Congress at Madrid, suggested the following regulations to be enacted into laws: (1) The law to declare the infection of any person with any form of venereal disease to be a crime. (2) That such crime against the person be punished by indemnification and imprisonment for a period of two years. (3) When the offender could not indemnify the injured person by bearing the expenses of treatment, that the term of imprisonment or transportation be increased. (4) That the brothel-keepers be made to indemnify any person infected on their premises or by any of their licensed women, and in case of insolvency of the brothel-keeper, imprisonment or fine should be enforced. Dr. Holton thought the rules of Prieto stringent enough to control the evil. However, to enforce them would require an enlightened and educated public sentiment. He would educate the medical profession and educate the public, and follow this work by the enactment of wise laws which the educated public sentiment would insist should be thoroughly executed.

This paper was discussed by Drs. John S. Fulton, George R. Dean, G. P. Conn, Frank Wells, E. W. Cooper and Charles O. Probst. The general trend of the discussion was the necessity of educating the medical profession and the public in regard to the terrible ravages of venereal diseases and the practicability of limiting their spread by legislative enactment.

Dr. PROBST, then offered the following preamble and resolution, which were adopted by the Conference:

*Whereas*, The great prevalence of venereal diseases, which is indirectly the cause of many deaths, is a matter of much concern to the public health; and,

*Whereas*, The communication of these diseases to innocent persons must be largely due to ignorance, be it

*Resolved*, That a committee of three be appointed by the President to prepare a leaflet that would be acceptable to physicians to give to their patients, setting forth the precautions to be taken by one suffering from a venereal disease to prevent its communication to others, and to make such other suggestions as it may deem proper. Such instructions, when adopted by this Conference, to be recommended to State and Provincial Boards of Health for dissemination among the medical profession, and said committee shall report at the next meeting. (Committee unannounced.)

**Another Year's Test of the Mosquito Doctrine of the Transmission of Yellow Fever in Havana**—Dr. JOHN GUITÉRAS of Havana, Cuba, said there had not been a case of yellow fever in Havana for the past two years except those that had been imported from other countries, chiefly Mexico. He then detailed the methods employed in combating this disease in Havana, which are familiar to our readers.

**Report of Committee on Promotion of Uniformity of Reports upon Vital Statistics.**—Dr. CRESSY L. WILBUR of Lansing, Mich., presented this report. In the division of labor between the committee representing this Conference and the committee of the American Public Health Association, American Medical Association, and others interested in the improvement of vital statistics, the special task had been selected of examining and reporting in regard to the forms of tables and general manner of presentation of statistical data employed in the annual, biennial, weekly, monthly, or other reports of States and

cities.[1] In this the U. S. Census Bureau had coöperated and had collected samples of the forms at present in use in nearly all of the registration offices of this country for the purpose of analysis and study by this committee. It was a difficult task to consider all of the forms in a comparative way, but it seemed desirable to do so before formulating a report as to the absolutely essential tables that were to be recommended for use in the various reports. The committee, therefore, reported progress and requested that additional time be granted for making a final report, which could probably be prepared before the next session of the Conference. In addition to the work outlined above, the committee had coöperated, on behalf of the Conference, with the committees of the American Public Health Association and of the American Medical Association, the U. S. Census Bureau, and the Public Health and Marine-Hospital Service, in the preliminary work for the coöperative study and improvement of the international classification of causes of death, a report upon which would be presented at the session of the American Public Health Association next week, and also for the extension of adequate registration laws. The report was accepted.

**Transportation of the Dead.**—The conference adopted a set of rules, which it was proposed should be established by legislative action, to govern the transportation of dead bodies.

**Officers.**—The following officers were elected for the ensuing year: *President*, Dr. John N. Hurty, Indianapolis, Ind.; *Vice-President*, Dr. John S. Fulton, Baltimore, Md.; *Secretary*, Dr. Garnder T. Swarts, Providence, R. I.; *Treasurer*, Dr. James A. Egan, Springfield, Ill.

The time and place for the next meeting were left to the officers of the Conference to decide.

## Medical Items.

**Contagious Diseases — Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 31, 1903:

| | Cases. | Deaths. |
|---|---|---|
| Measles | 193 | 6 |
| Diphtheria and croup | 274 | 29 |
| Scarlet fever | 84 | 7 |
| Smallpox | 1 | ... |
| Varicella | 23 | ... |
| Tuberculosis | 278 | 167 |
| Typhoid fever | 100 | 18 |
| Cerebrospinal meningitis | ... | 3 |

**Coffee-Drinking.**—A recent number of the *Lancet* contains a philosophic dissertation on coffee-drinking, pointing out that coffee seems to suit some individuals, while it injuriously affects the digestion of others. The article proceeds as follows: "The excessive drinking of coffee is, in any case, an evil. But it is often forgotten that coffee can be taken in other ways, and in none better than in the form of jelly. A clear coffee jelly after dinner is every bit as good as the hot infusion, while it is free from some of the drawbacks of the latter. Coffee, unlike alcohol, diminishes organic waste, rouses the muscular energy without the collapse which follows alcoholic inhibition and gelatin in the form of jelly is cooling, assuages thirst, is soothing, and has a tendency to absorb any excessive acidity of the stomach. Gelatin is what is known as a 'proteid sparer'—that is, it saves the destruction of proteid such as albumin. Having regard to these facts, therefore, coffee jelly should form a very suitable sequel to dinner, and an excellent substitute for the infusion. Moreover, the astringent principles of coffee, which, however, are different in kind and degree from those present in tea, are nullified by the gelatin. In short, gelatin is an excellent vehicle for coffee, but, as is necessary in making the infusion, the quantity of coffee in the jelly should not be stinted. Coffee serves an admirable purpose in dietetics, and those with whom it disagrees when taken in the form of a hot infusion will, very probably, find the jelly quite satisfactory.

**Nutritive Value of Sugar.**—M Dastre writes in the August number of the *Revue des Deux Mondes* on this subject. He shows that instead of being a kind of relish making other foods palatable, sugar performs an important function in making good the losses caused by muscular exertion and in maintaining the human body in health and vigor. M. Dastre endeavors to prove that the processes of life in the higher vertebrate animals must be carried on in a sugary solution of 1½ to 1,000. He also takes the view that glucose, which is supplied to the body by means of sugar, is the source of muscular energy.

**Health Report.**—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 31, 1903:

SMALLPOX—UNITED STATES.

### GONORRHŒA IN INFANTS, WITH A REPORT OF EIGHT CASES OF PYÆMIA.*

BY REUEL B. KIMBALL, M.D.,
ATTENDING PHYSICIAN TO THE BABIES' HOSPITAL, NEW YORK.

ALTHOUGH gonorrhœa has probably been as widely studied as any disease during the past hundred years, and it is now almost a quarter of a century since Neisser first isolated the micrococcus gonorrhœa, the medical profession is only on the threshold of its knowledge of the manifold forms which this infection may assume. The importance of the gonococcus as a pyogenic organism has long been underestimated. It is of interest to note how our conception of this disease has widened with our knowledge of the different forms it may assume. It has been studied as the cause of a specific urogenital infection, of ophthalmia, of pelvic inflammation in women, of arthritis, of peritonitis, and of endocarditis.

Gonorrhœa, as a medical term, has been raised from the title of a local inflammation of a mucous membrane to the dignity of a systemic infection. The gonococcus is now feared as one of the most dangerous of microorganisms, whose presence in the human body may be attended by serious and uncontrollable results.

Gonorrhœal infection in infants is a field that of late years has been particularly open to investigation. Medical journals, and especially journals of pediatrics, are full of articles on this disease in children. Much, however, of the literature deals with infection in the newly born, in which the disease in the mother is the obvious cause of the ophthalmia or vaginitis in the offspring. Vulvovaginitis, urethritis, and arthritis are also reported in infants and in older children in whom such a source of contamination cannot be shown. But we do not believe that the medical world at large realizes the extent to which gonorrhœa occurs in children and in infants, nor the different and peculiar forms which the disease takes in these little ones, nor the danger and comparative ease of contagion.

There can be no doubt that there exists in infants a remarkable predisposition to infection with the gonococcus. The satisfactory explanation of this is still in doubt. It may be due, in part, to the imperfect development of the mucous membrane in infants, but it is certainly also to be explained by the relative prominence of the unprotected vulva in in females, and to the constant handling of infants which is necessary for cleanliness. In girls the susceptibility is inversely as the age of the child, very young infants being more liable than older infants or children. This predisposition is not confined, however, to females, being observed also in males, in whom it can be less satisfactorily explained.

Vulvovaginitis is the bane of all institutions in which infants and children are grouped together. The infection once introduced, spreads with incredible rapidity, attacking practically all the females, and unless great precautions are taken, some of the males. This is the experience of all who have charge of infants' wards in hospitals or institutions; and applies equally to schools, public baths, asylums, etc. One of the worst cases of gonorrhœa I ever saw was in a child eight years old, and was acquired in a fashionable school in this city.

The record at the Babies' Hospital during the past twelve months substantiates the truth of this statement. During the last year there have been six hundred admissions to the public wards, and among these patients we have had seventy cases of vulvovaginitis, and ten cases of arthritis, due to the gonococcus. Only one case of gonorrhœal ophthalmia has arisen in the hospital. A large proportion of the vaginitis cases were infected while in the hospital. Possibly one-tenth of the entire number were admitted with the disease and in every case became the source of a small epidemic.

The infection has been stamped out half a dozen times, and has reappeared after some weeks of immunity in a most discouraging fashion. We hope that now our preventive measures are such that no such patient can enter the hospital, and that if in any unforeseen manner we should admit a case, it would be impossible for the disease to spread. For three months every girl admitted has had a smear taken from the vaginal secretions and examined microscopically for gonococci before she is received into the wards. On the slightest suspicion of a vaginal discharge occurring in a ward patient every female in the hospital is reëxamined and another microscopical examination is made from every child. By this means we exclude chronic cases of vaginitis without local symptoms and cases in which the discharge has not yet appeared. We are especially careful in admitting cases from other institutions and day nurseries. Also cases of simple non-specific vaginitis should be carefully watched, as there seems to be more danger of inoculation when a local inflammation exists.

In dealing with cases in the hospital we have found that only complete isolation can absolutely prevent the spread of the disease. It may be possible to keep older children with gonorrhœa in a general ward and have no unfortunate consequences, but with infants, in whom constant handling is essential to cleanliness, our experience does not justify this. We now isolate infected children, whether the trouble is vaginal or arthritic, in a separate room, and with separate nurses. Even if utmost precautions are taken to keep apart all clothing, wash cloths, thermometers, nursing bottles, etc., the carelessness of a single nurse, with insufficiently sterilized hands, may undo, in an instant, the value of these regulations. If, however, it is necessary to keep such an infectious case among other children, the sterilization of the napkins is an essential feature of the prophylaxis. But even this often fails, and recently we have adopted the plan of using sterilized opera cloth for all of the girls, and having it immediately destroyed. With

*Read before the Clinical Society, May 22, 1903.

infants, however, in whom frequent changing is required, this becomes a serious item of expense.

We have found that in children under one year of age, gonorrhœal vulvovaginitis yields readily to treatment, ten days being the duration of an ordinary case. In older children the disease is much more persistent and less amenable to treatment. After trying a number of antiseptic douches we have found that protargol, from 2 to 5 per cent., gives the best and most uniform results.

Among the cases of arthritis or pyæmia which have been mentioned before, eight are worthy of further consideration. In enumerating these cases we exclude all those in which a general systemic infection has followed a local catarrh, either of the vagina or of the conjunctiva. The literature furnishes numerous examples of such extension of the disease, and in no way does such an infection differ from similar instances in adults. The important point is that *in these eight cases of pyæmia there was no local infection which could be considered to form a starting point for the disease*—that is, these joint inflammations and abscesses developed, as it were, out of a clear sky, having been discovered in children who were not suspected of harboring the gonococcus, who had no inflammation nor discharge from any mucous membrane, and in whom the most careful scrutiny could not fix the portal of entry of the organism. So far as we have been able to learn, no similar instances have been reported in the literature, and in view of the seeming importance of the subject, we will give a detailed report of the findings in these cases, in addition to the histories appended.

Case I.—Female, aged three months. Family history negative; personal history negative. Admitted to the Babies' Hospital, June 18, 1902, for an acute attack of enterocolitis. On admission: weight, 8 pounds 1 ounce. Physical examination negative. No vaginitis nor conjunctivitis. Until June 28 child showed only the symptoms of a mild enterocolitis, with slight temperature.

On June 28 the temperature rose to 105°, and then fluctuated between 104°-101° until July 11, when it became subnormal until just before death.

June 29: Left knee and hand swollen, red, hot, and painful. Wet dressings applied.

July 1: Both knees and both hands enlarged, red, and tender. No fluctuation. Leucocytosis marked.

July 2: On outer side of both ankles over malleoli there is a reddened area of intense heat. General œdema of entire body.

July 3: Knees less swollen.

July 4: No redness of joints, except right ankle.

July 5: Fluctuation obtained over right ankle. Ankle aspirated, and a drop of thin yellow pus obtained. Examination of urine negative.

July 7: Ankle-joints still swollen and tender, inflammation of other joints subsiding.

July 9: Swelling of ankle-joints increased.

July 10: Aspiration again of right ankle, and about ten drops of thick yellow pus obtained.

July 12: General œdema extreme. Patient died at 8.45 A.M. The child never at any time had any discharge from the vagina or eyes, or any symptoms of inflammation of these mucous membranes.

*Bacteriological Report by Dr. Berry.*—Smears made from the pus obtained from aspiration of right ankle, on two separate occasions, showed, microscopically, diplococci, both free and grouped, in cells which decolorized by Gram stain. No cultures made. Smears made from the vagina were negative for gonococci.

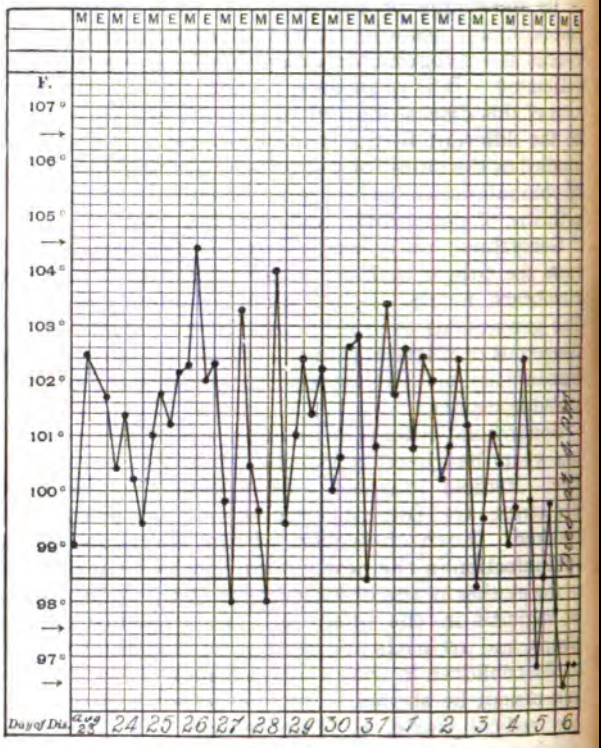
*Autopsy by Dr. Berry.*—Marked general œdema. Lymph nodes of right cervical region enlarged and congested.

*Joints.*—The right shoulder on deep incision yielded about 4 c.c. of thick green pus. Left shoulder, a few drops of pus in deep tissues about joint. Both wrists, drops of thick pus between the muscles of dorsum of hand, and in tissues about articulations, but the joints were apparently not involved. Elbow-joints free. Hip-joints not incised. Right knee, no pus in joint, but between the muscles a few flecks of pus obtained. Left knee free. Right ankle, fluctuation over external malleolus. Incision opened up an abscess cavity 2 by 2 cm., base formed by the periosteum of small bones. Contents a thin greenish purulent fluid. The muscles and ligaments of the foot infiltrated with pus. Left ankle-joint free.

*Thorax.*—On the posterior surface of the sternum, at second rib, a small ragged ulcer. 1½ by 1 cm., covered with greenish pus. Heart and pericardium normal.

*Lungs.*—Showed scattered areas of bronchopneumonia and atelectasis. Bronchial lymph nodes not enlarged.

Other organs practically normal.



Case II.—G. McG., æt. 2 months.

Case II.—Male, aged two months. Family history negative. Personal history not obtained. Admitted to the Baby's Hospital August 11, 1903. On admission physical examination negative. Weighed eight pounds ten ounces. No discharge from eyes or urethra; child suffered from colic and indigestion.

August 23: The forefinger of the left hand, the right great toe, and the right wrist swollen, red, and painful.

August 26: Œdema of right side of face. Regular elevation of temperature for past three days.

August 30: Left ankle and foot much swollen, fluctuation above the ankle-joint.

September 1: Left ankle incised and about a drachm of thick yellow, tenacious pus evacuated. Incision made over the dorsum of the right hand, and an abscess opened up which extended to the little finger-joint. Considerable pus in abscess.

September 5: Second joint of the forefinger opened, and several drops of pus pressed out. General œdema marked.

September 6: Child died.

*Microscopical Report by Dr. Berry.*—Smears of pus obtained from joints showed gonococci within the leucocytes.

*Autopsy.*—Forty-four hours after death. Marked general œdema. Brain normal. Beginning bronchopneumonia in lungs. Fibrinous pleurisy. Other viscera normal.

All the large joints were opened, and pus was present in the right ankle, elbow, and hip. There was a purulent infiltration in the muscles of the left foot.

Cultures were made, but were not satisfactory, owing to removal of the laboratory from the country to the city.

Case III.—Male, aged three months. Family history negative. Personal history: always delicate; nursed two weeks; since then fed on condensed milk. Has steadily lost weight for one month. Stool normal. Admitted to the Baby's Hospital, December 4, 1903. On admission, weight five pounds. An undersized poorly nourished child. Eyes normal. No urethritis. Physical examination negative. For two weeks the child showed no symptoms other than those common in marasmus.

December 20: Temperature was 101°; first since admission.

December 22: The right knee-joint was much inflamed, swollen, and hot to the touch.

December 26: The right-knee was aspirated and about 2 c.c. of thick, greenish pus obtained. There was a slight fever up to December 28, but after that the temperature was subnormal until death. No other joints involved.

January 2: The child died, with the symptoms of inanition.

*Microscopical Report by Dr. Cordes.*—Films from the pus obtained by aspiration showed extra and intracellular diplococci which decolorized with Gram stain. Cultures made on ascitic fluid-agar showed, in forty-eight hours, small, round colonies on the edges of the collections of pus. The growth was scant and short-lived. Transplantations from the growth to other media did not succeed. Film from the cultures showed large numbers of decolorized diplococci, by Gram stain.

*No autopsy* was permitted.

Case IV.—Male. Age ten weeks (on admission). Family history negative. Personal history: normal infant, nursed seven weeks, then fed on milk and water. Mother in hospital (operation). Admitted to the Babies' Hospital December 12, 1902, for neglect. On admission, weight nine pounds. Physical examination, with the exception of Erb's palsy, negative. Child has been circumcised. Urethra normal, no discharge. Eyes normal. No conjunctivitis. During first two weeks in hospital, no especial symptoms. Child had had *considerable thrush* in mouth.

December 25: Right knee became enlarged, inflamed, and painful. Temperature 102°—before this normal.

December 26: Right knee more swollen. Aspirated and several c.c. of thick, yellow pus drawn off. Temperature still elevated.

December 31: Right knee and thigh greatly swollen. Temperature slightly elevated every day.

January 3: Right knee still swollen, again aspirated and no pus obtained. Leg put up in splint.

January 21: Splint removed, leg stiff, slightly swollen. No fluid in joint. Temperature now normal.

From February 1 on the child gradually lost ground, took food badly, stools fairly normal.

March 1: Died. Symptoms of inanition.

*Bacteriological Report by Dr. Cordes.*—Smears, from pus aspirated from right knee December 26, showed numerous intracellular diplococci, which decolorize by Gram stain.

Cultures made from the pus in the ordinary glycerin, and glucose-agar media did not grow..

Culture made on ascitic fluid-agar, in forty-eight hours, showed numerous small, almost translucent, colonies on the surface of the media. Smears from these colonies showed similar diplococci which decolorize by Gram stain.

Case V.—Male, age two months (when admitted). Family history: Father has had syphilis. Mother healthy, denies gonorrhœa. Personal history: Has always had the snuffles. Breast-fed. Vomits a good deal. Stools normal. Admitted to the Babies' Hospital, December 19, 1902, for syphilis. On admission: Weight, nine pounds and eleven ounces. Child had a syphilitic rash and *mucous patches* in the mouth and about arms. No conjunctivitis or urethritis. The child lay in a bed next to a severe case of gonorrhœal vaginitis.

December 28: Left knee slightly enlarged. Temperature very high for past two days (103°), though before this there had been irregular fluctuations.

December 29: *Thrush in mouth.* Mucous patches have disappeared under treatment. Left ankle swollen and painful.

December 30: Right ankle red, swollen, and painful.

January 3: Temperature still irregularly elevated. Ankles fluctuating. Incision made below both outer malleoli and about 1 c.c. of creamy pus evacuated.

January 15: Left shoulder painful and swollen. Child is vomiting and taking food badly, temperature still high.

January 18: Both shoulders enlarged and fluctuating, swelling running down under the bicipital muscles. Ankles have healed.

January 19: Abscesses on arms opened by an incision over bicipital insertion. Large amount of thick, yellow pus pressed out of shoulder-joint.

January 21: Small fluctuating mass over the occiput.

January 22: Occipital abscess opened and evacuated. Temperature still elevated.

January 29: Temperature normal. Incisions all healed. Takes food well. Stools normal.

February 10: A large swelling noted to-day on inside of left thigh, above the middle. Swelling is hot, hard, and painful. Temperature still remains normal.

February 16: Swelling below left hip is growing smaller.

March 1: No new joint involvements on abscess. Child is failing, vomits a good deal. Stools normal.

*Bacteriological Report by Dr. Reed.*—Pus from the ankle-joints and shoulder-joints showed in smears degenerating leucocytes, many of which contained small, slightly biscuit-shaped diplococci which decolorize by Gram. No other organisms observed.

Cultures made from thick pus from these joints on the plain agar and glucose agar did not grow. Cultures made on ascitic fluid agar showed, after forty-eight hours' growth, very small, pin point to pin head, almost translucent colonies. In one specimen a transplantation of the growth was successfully made on ascitic fluid-agar. The growth in every case was delicate, scarcely visible in twenty-four hours, and most satisfactory after four or five days' growth. Smears from these cultures showed in every case a diplococci, occasionally in tetrads, never in chains, which decolorize by Gram stain.

January 9: Microscopical examination of exudate in mouth showed typical thrush.

*Microscopical examination of smears* from the eye and urethra failed to show diplococci.

Smears made from the mouth and tonsils showed, on staining, numerous leucocytes containing biscuit-shaped diplococci which decolorize by Gram stain. It was impossible to isolate the organisms in culture. The presence of cocci in the normal secretions of the mouth, which have the same morphological and staining reactions as the gonococci, make it impossible to lay any stress on this finding, although it is quite possible that the organisms here observed were true gonococci.

Case VI.—Male, age ten weeks. Family history negative. Personal history: delicate from birth, no history of ophthalmia. Nursed one month. Then fed on boiled milk and water. Vomits a great deal. Admitted to the Babies' Hospital January 14, 1903. On admission, weight nine pounds. Physical examination negative. Eyes normal. No conjunctivitis. Child had been circumcised. No urethritis For the first two weeks the child showed only symptoms of a severe feeding case.

January 29: Temperature rose to 103°. Previous to this no fever. The right ankle was swollen, red, and painful. The right great toe was also inflamed.

January 31: The left ankle became involved, the temperature remaining elevated.

February 1: The right wrist was swollen and red.

February 2: Temperature still irregularly elevated. Stools frequent and contained mucus. Second toe on right foot conspicuously red and tender.

February 8: Second toe on right foot opened and several drops of creamy pus squeezed out of second joint. Ankles and wrists still swollen and painful.

February 11: Fluctuation obtained in left ankle joint, which was superficially incised below outer malleolus. A small amount of pus was squeezed out of pockets, presumably in the tendon sheaths. The joint was not opened.

February 13: Right shoulder-joint swollen and painful. Right toe has healed completely. Ankles and wrist less swollen. Temperature still high.

February 14: Incision made over right bicipital insertion, almost half an ounce of thick, stringy pus pressed out of arm. Shoulder-joint apparently not involved.

February 18: Joints less swollen. Left ankle healed. Temperature falling.

From this date on temperature was normal. The joints previously noted as inflamed subsided. The right shoulder-joint on March 2 was found full of fluid, enlarged and painful.

The general condition of the child is poor.

Takes food badly. Losing weight. Stools normal.

*Bacteriological Report by Dr. Reed.*—Pus from toe joint and abscesses about the ankle-joints and shoulder-joint show, in smears, intracellular diplococci in great numbers, decolorizing by Gram. Cultures made from these joints, on the ordinary agar, glycerin-agar and glucose-agar failed to grow. Cultures on ascitic fluid-agar showed, in every case, small, almost translucent colonies, very slow in growth, which in smear consisted of diplococci, decolorizing by Gram stain.

Microscopical examination of smears made from the urethra, eyes, and mouth in this case failed to show any diplococci which were Gram negative.

Case VII.—Male, age two and one-half months. Family history: father consumptive. Mother denies gonorrhœa. Personal history, born at the New York Lying-in, which reported the child as perfectly well at birth and for first two weeks. Positively no ophthalmia. Nursed only two weeks. Then fed on various kinds of milk preparations, none of which agreed with him. Admitted to the Babies' Hospital, January 28, 1903, as a case of malnutrition. On admission, small, poorly nourished, pale infant. Weight seven pounds, three ounces. Physical examination practically negative. Eyes normal. No conjunctivitis. For the first ten days after admission the child showed no remarkable symptoms—began to take food well, stools normal.

On February 9 the child's temperature rose to 102°, the first elevation since admission. Considerable thrush was found in the mouth.

On February 11 the left wrist was noticed to be red, swollen, and painful.

On February 12, both ankles, right knee, left wrist, and little finger were swollen and painful.

Up to February 14 the temperature was irregularly elevated from normal to 102° each day.

From February 14 until death there was no fever.

February 16: Both knees were swollen and fluctuating.

February 16: Left wrist and little finger were opened—creamy yellow pus was found in large quantities, apparently from the tendon sheathes in the wrist and from the joints of the little finger.

February 18: Child died, temperature normal. No especial symptoms. Joints still swollen.

*Bacteriological Report by Dr. Reed.*—Smears from the pus obtained from the finger and wrist showed numerous intracellular diplococci, which decolorized by Gram stain. Cultures made from wrist abscess on glucose agar, acid agar, milk and plain bouillon showed no growth. Cultures made in ascitic fluid bouillon in twenty-four hours were cloudy, and in smears showed numerous diplococci decolorizing by Gram. Cultures from finger-joint would not grow on glycerin agar, but on ascitic fluid agar showed the typical delicate growth of small, almost translucent, colonies, which in smear preparation consisted of small diplococci decolorizing by Gram. Smears from the urethra and eyes under microscopical examination were found negative for gonococci.

*Autopsy by Dr. Wollstein*—in thirty hours after death: The body was emaciated and œdematous. There were small abscesses in the scalp, under the skin of the chest wall, and between the larynx and the hyoid bone. On incising the larynx, there was a purulent infiltration in the posterior wall between the mucous membrane and the thyroid cartilages. There was pus in the right wrist and left little finger. The viscera were normal, with the exception of a beginning bronchopneumonia.

*Bacteriological Findings.*—A Gram negative diplococcus was found in smears from the abscesses in the skin and about the larynx and from the laryngeal mucus. No films were made from the joints. Cultures from the heart's blood and kidney were made on ascitic-glucose agar, no growth obtained. Cultures made from the pus outside of the larynx—on ascitic-glucose agar, developed a few fine bluish-white colonies. This growth was transplanted successfully to serum agar, but failed to grow when transplanted on neutral glycerin agar. Films from these cultures showed a diplococcus, decolorizing by Gram stain. Cultures made from the outside and inside of the larnyx on glucose agar failed to grow. Cultures from the lung showed staphylococcus pyog. aureus.

Case VIII.—Male, age five weeks (on admission). Family history negative. Personal history: healthy at birth. Did not have ophthalmia. Nursed two weeks, then fed on an artificial food. Losing weight, vomiting all food. Admitted to the Babies' Hospital January 28, 1903. On admission, weight

seven pounds two ounces. Physical examination negative. Child has been circumcised. No urethritis or signs of inflammation, no discharge. Eyes normal. No conjunctivitis.

February 10: Temperature elevated for first time.

February 11: Left wrist swollen and painful. Temperature 102.4°.

February 12: Slight conjunctivitis of left eye. Both knees and left wrist swollen and painful.

February 14: Left ankle swollen and hot.

February 15: Eye apparently healed. Temperature still irregularly elevated.

February 16: Left wrist incised—stringy yellow pus pressed out of pockets, probably from tendon sheaths.

February 18: Right knee greatly swollen, joint aspirated several c.c. of greenish, thin pus withdrawn. Left knee and temperomaxillary joint swollen.

February 23: Stools thin and frequent. Temperature now normal. Right temperomaxillary joint opened—several c.c. of pus pressed out.

February 26: Small swelling over tendon of left biceps. Other joints have subsided.

February 27: Abscess on left arm opened and considerable pus evacuated. Shoulder-joint apparently not involved. Bloody discharge from right ear. Stools normal. Temperature practically normal.

March 3: Small abscess over prominent point on left parietal bone. Center fluctuating.

*Bacteriological Report by Dr. Reed.*—Smears from the pus from abscesses about wrist and arm, from knee-joint and temperomaxillary joint showed numerous intracellular, biscuit-shaped diplococci, decolorizing by Gram. Cultures made on ascitic fluid-agar, ascitic fluid-bouillon, and placental blood-agar in forth-eight hours, showed a growth of typical diplococci decolorizing by Gram. The colonies on the blood-agar were larger and appeared sooner than those on ascitic fluid-agar. Microscopical examination of smears from the urethra, mouth, and ear failed to show any diplococci. Gram, negative. Smears from the left eye, February 13, showed typical gonococci. This eye developed after the joint involvement.

To summarize briefly the preceding eight cases: all were in infants under the age of three months. Seven were males and one was a female. It seems to be a very remarkable fact, that so many males should be affected, whereas out of over seventy females with well-marked vaginitis there was but one case of secondary gonorrhœal arthritis.

In six of these cases there was a purulent polyarthritis, periarthritis, and myositis, the disease being apparently a general pyæmia. In two cases only one joint, the knee, was involved. The ankles and wrists were the favorite seat of inflammation. In two cases the temperomaxillary joints were involved, and in three cases toe or finger-joints. In one case, which came to autopsy, eleven joints were found to contain pus.

The treatment in every case was incision (arthrotomy) or aspiration, wet dressings being applied to the affected parts. The rapidity with which the incisions healed and the joints were restored to normal was remarkable. The joints usually developed one after the other, the first healing often before the last became affected.

In none of these cases was there any urethritis, vaginitis, or conjunctivitis, with the exception of an ophthalmia in one instance (No. 8), which developed after the joint involvement. The mucous membranes of the eye, urethra, and vagina were apparently normal.

No history was obtained of gonorrhœa in the parent, nor of ophthalmia at birth, nor of other gonorrhœal manifestations in the child.

Microscopical examination of the pus obtained from the various joints affected in these eight cases showed, in every case, numerous diplococci somewhat biscuit-shaped, situated within leucocytes or free in the serum. These diplococci decolorized by the Gram stain, No other organisms were ever seen. Cultures were made from the pus obtained from the various joints in all the cases. No growth was obtained on any of the ordinary culture media, *i.e.* plain agar, glucose agar, bouillon, milk. In the last six cases growths were obtained by using media made from human sera, *i.e.* ascitic-fluid-agar and bouillon, and small colonies appeared in about forty-eight hours. Smears from these growths showed the same diplococci which decolorized by Gram's stain. In the first two cases no cultures were made on the special media, but no growth was obtained on the ordinary media. The organism was never transplanted successfully more than one generation.

Blood cultures were made in two cases, on serum media—but no growth was obtained. Animal inoculation was attempted intraperitoneally in one case. The animal still lives, four months after the injection.

Six of the cases have already terminated fatally; four of the deaths occurring during the acute stage of infection. The two other children died of marasmus several weeks after the joint affection had subsided. The two surviving children have now no signs of pyæmia, but their general condition is so poor that their final recovery is extremely doubtful.

Autopsies were obtained in three cases. The arthritic lesions, previously described, with purulent infiltration of the muscles about the joints and a slight bronchopneumonia were found in every case. In one case (No. 7) there was a purulent infiltration in the posterior wall of the larynx and two small abscesses between the larynx and the hyoid bone. Biscuit-shaped diplococci decolorizing by Gram were found microscopically in the pus and in the smears from the laryngeal mucus. Cultures from the abscesses were made on ascitic fluid-agar and on the ordinary media. A similar diplococcus was grown on the first medium; there was no growth on any of the other tubes.

The organism isolated from the abscesses and joints during life and from these autopsy cases were undoubtedly the gonococcus. Every possible effort has been made and every control used to establish the truth of this fact. Both the smears and the cultures from the pus were finally sent to the Johns Hopkins Pathological Laboratory and our diagnosis confirmed by Prof. W. H. Welch. During the epidemic these cases were under observation by Dr. Holt, in whose service many of them occurred, and to whom I am greatly indebted for the privilege of using them.

A remarkable feature of this series of cases is that we apparently have eight cases of gonorrhœal pyæmia without any perceptible involvement of a mucous membrane to afford a point of entrance for the organism to the general circulation.

Reviewing the possible portals of entry to the body, we believe we can exclude the skin and umbilicus in these cases, as there was no lesion of surface epithelium or sign of cord infection in any case.

The urethra and eyes in these pyæmic cases were invariably normal, and the microscopical examination of the secretions was negative.

The anus in one case (No. 5), which was syphilitic, may have been the source of infection. In no other case was there evidence of any rectal or gastrointestinal disease.

A stomatitis, like thrush, was present in the mouth of three of the children, and in one of these syphilitic mucous patches also existed. In one case intracellular diplococci, decolorizing by Gram, were found in the mouth-scrapings; but it was impossible to isolate the organism and prove it to be the gonococcus by culture. The findings in this one case were so suggestive that a hasty search was made through the literature to find if the aroused suspicion that the gonococcus could cause a stomatitis, and from this a general pyæmia was substantiated by similar cases.

Gonorrhœal stomatitis in the new-born and in infants is a disease of which we have numerous instances reported in this country and abroad. Dr. Kraus, in the Nothnagel-Series, discusses the subject briefly, describing the characteristics of the inflammation. He pointedly remarks that as yet there are no cases reported of visceral manifestations following this form of gonorrhœa, as in the urethral and vaginal infection, but that the cases on record are still few and were easily cured.

These cases of pyæmia in which the only inflammation of a mucous membrane was in the mouth are certainly suggestive of such a mode of general infection.

The possibility of a respiratory portal of entry is strongly indicated in one case (No. 7) in which the infiltration of the trachea was found at autopsy, and the gonococci were grown in cultures from the mucous membrane and from the abscesses in the adjacent tissues. During life this case had suffered severely from stomatitis. The infection undoubtedly must have occurred in all severe cases through a mucous membrane; and the evidence, such as it is, points to the mouth or larynx as the most likely point of entrance for the organisms. The evidence is principally negative—the mucous membrane of the mouth and respiratory tracts only exhibiting lesions in three cases, and not of such severity as to be perceptible on ordinary examination; but no other mucous membrane of the body showed evidence of disease, except in the one syphilitic case. This mode of infection, which has hitherto been thought impossible, we believe to have occurred from contamination by the nurse's hands during the necessary cleansing of the mouth. In the usual routine observed in washing children in the Babies' Hospital, the mouth and eyes have been the first parts attended to and the lower part of the body the last; a rigid adherence to this order would, of course, make a mouth infection impossible. We regret to say, however, that there is strong evidence that this is not the order always observed, careless nurses sometimes washing the mouth last. This is another example of the extreme ease with which slight negligence may lead to serious results in starting an epidemic of an alarming nature.

### Conclusions.

1. Gonorrhœa prevails among infants and children to an extent not fully appreciated by the medical profession at large, and has become a common epidemic in institutions where numbers of children are placed together.

2. The ordinary clinical forms which the gonococcus infection assumes in children are ophthalmia, vulvovaginitis, and pyæmia.

3. A series of cases of pyæmia, reported in this paper, occurred in infants, in whom no local lesion could be found to explain the mode of entrance of the organism to the general circulation.

4. The suggestion is made, that from a stomatitis due to the gonococcus such a systemic infection may arise. Gonorrhœal stomatitis in infants is a disease that needs further study.

5. Only by careful exclusion, by microscopical examination, and by complete isolation can this disease be absolutely debarred from a hospital where infants are cared for.

6. There is urgent need of public enlightenment on this subject. Those in charge of institutions for children, trained nurses and even parents, should be taught the frequency and virulency of this infection and the ease with which it is spread. It should be the duty of health authorities to include gonorrhœa among the acute infectious diseases of children.

The writer is indebted to Dr. Dorothy Reed, resident physician at the Babies' Hospital, for the bacteriological work and other valuable assistance in the preparation of this paper.

## TERMINAL SYPHILIS AND TABES.

By WILLIAM J. DOUGHERTY, M.D.,
NEW YORK.

NEUROLOGIST TO ST. JOSEPH'S HOME FOR THE AGED; PHYSICIAN TO ST. VINCENT'S HOSPITAL (OUT-PATIENT DEPARTMENT); ASSISTANT IN THE DEPARTMENT FOR NERVOUS AND MENTAL DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

There is probably no organic disease of the nervous system which admits so readily of diagnosis as does typical tabes dorsalis, locomotor-ataxia, or as it is sometimes called posterior spinal sclerosis; and it can be said with equal truth that in its earlier stages, it is five times out of ten wrongly diagnosticated. This latter fact strongly impresses itself upon anyone who devotes especial attention to the study of nervous diseases, and the only explanation that suggests itself, is that practitioners, notwithstanding the relative frequency of the disease, have failed to familiarize themselves with its earlier and less obtrusive signs and symptoms.

The term "tabes dorsalis" was used by ancient writers not in the sense now employed, but to indicate a wide diversity of ailments depending most often on sexual excess. Our present conception of tabes dates from the middle of the nineteenth century, when through the writings of Todd in England, Romberg in Germany, and Duchenne in France the profession was taught a general knowledge of this affection. Since their time important contributions to the subject, especially clinical, have been made by many clinicians; of these Argyll-Robertson, in 1869, described the pupillary phenomenon which bears his name and which consists in a non-responsive condition of the pupil to light; and Westphal, in 1875, who pointed out that the knee-jerks of tabetics were absent.

Much has been written on the etiology of tabes, and since Fournier and Erb established the connection between syphilis and this disease it has been quite generally conceded by competent observers that a previous luetic infection is necessary, in most cases at any rate, for the development of tabes. There are but few, however, who admit that tabes is exclusively dependent upon a previous luetic infection; that is, most neurologists hold that there is *something* other than previous syphilis necessary to cause the disease. This something may be a neurotic predisposition or it may be a diathesis.

At present syphilis is looked upon only as an indirect cause of tabes. In other words, tabes is classed not as syphilitic but as a parasyphilitic disease, and this has recently been defined as "a disease syphilitic in origin but not in nature." The term parasyphilis was introduced by Fournier, and

is intended to convey the idea that diseases thus designated are dependent upon syphilis though themselves not syphilitic. I consider this term parasyphilis as vague and misleading (at any rate in so far as it applies to tabes and general paresis), and would suggest in its stead the designation TERMINAL SYPHILIS. This expresses more aptly what in reality we are justly entitled to believe is the true state of affairs; namely, the changes indicating the terminal activity of the syphilitic virus. Again it is more in accord with our present terminology of syphilis, which admits of primary, secondary, and tertiary stages, and which would be uniform and complete with the addition of a terminal stage. Ogilvie,* in an address on parasyphilis, delivered before the Fourteenth International Congress of Medicine at Madrid in April of this year, said "The theory of parasyphilis is bound to lead to direct opposition with facts, because the premises upon which it is reared are fallacious and because it is based on a wrong notion of specificity."

The chief reasons advanced in opposing the syphilitic nature of tabes and at the same time tending to justify the usage of the term parasyphilis may be briefly summarized as follows: (1) The statistics of tabes which always contain a percentage of apparently non-syphilitic patients. (2) The morbid anatomy of tabes which is said not to exhibit the lesions of syphilis. (3) Uselessness of anti-syphilitic medication in the treatment of tabes. (4) The rarity of tabes as compared with syphilis. (5) The comparatively infrequent occurrence of tabes in races in which syphilis is very prevalent (Chinese, Negroes, etc.), and (6) the infrequency of tabes among prostitutes.

At first glance the above facts seem to constitute a convincing argument that tabes is not a syphilitic affection. I take it, however, that a comparative analysis of these facts tend rather to prove than to disprove the luetic origin and nature of tabes.

It is true (as the accompanying table taken from an article by Collins *Medical News*, January 3, 1903, shows) that a certain small percentage of tabetics

| | Men and Women. | | | |

apparently never have had syphilis, but when we consider how easy it is for one to have been infected with syphilis and not know of it, or through diffidence deny it; does it not seem remarkable that the percentage of tabetics denying an antecedent syphilitic history is not far greater? Fournier, in examining thirty-six patients suffering from gumma of palate, found that of this number 44 per cent. denied all knowledge of ever having been infected with syphilis; from this are we to conclude that gummata are not in nature, necessarily syphilitic? Unless we do, we are inconsistent and illogical in employing similar facts as arguments in an attempt to prove that tabes is not a syphilitic disease. Recently I saw a man recovering from spinal lues who was positive he had never had syphilis, and so far as I could elicit he apparently never had given the least evidence of it prior to the development of the condition from which he was then recovering. I do not relate this case because it is in the least uncommon, for similar examples are familar to all who see any considerable number of nervous patients—in fact, I have seen more patients with cerebral or spinal syphilis than I have tabetics, who denied a luetic history.

One naturally asks why so many are ignorant of having suffered an infection that is generally looked upon as producing a characteristic lesion at at the seat of its inoculation, and yet is followed by secondary manifestations that make the diagnosis certain. One, and the least important, reason for this I have referred to before; namely, a wilful denial on the part of some patients (especially women), owing to a desire not to incriminate themselves. Another and a more important reason is that syphilis in a considerable number of cases occurs as an extragenital infection, and still another and almost equally important factor is that syphilis need not necessarily produce at the seat of its inoculation reactions in the tissue that are suggestive in the least of chancre. Finally the secondary manifestations generally looked upon as necessary to corroborate the diagnosis of syphilis may be so slight as to escape the notice of the patient or may be wanting altogether.

Ignorance of a syphilitic infection may in some be due to the fact that the disease was contracted in early life. During the present year I saw three children, all girls under the age of five, suffering from syphilis contracted from their parents. If in later life these children should develop tabes they would, of course, deny ever having had syphilis. How many similar cases are embodied in the statistics we have at hand it is impossible to estimate, but to conceive that there are some requires no great stretch of the imagination.

In asserting so positively that the lesion of tabes is not in nature syphilitic we fail to take into consideration the fact that the infectious agent of syphilis has not as yet been recognized; such being admittedly true, how can we so confidently assert that this lesion is syphilitic and that one is not? That this fact be more forcibly impressed upon us we have but to go back a few years when it was customary to find the profession asserting with the same positiveness in the case of diphtheria that certain lesions were diphtheritic and others were not; but since the discovery of the Klebs-Loeffler bacillus it has been clearly demonstrated that in a strict sense there is no such thing as a characteristic lesion of diphtheria. It is true the typical early and many of the later lesions of syphilis are quite easily recognized, but are we to say the lesion of tabes is not syphilitic because it does not resemble these?

I believe a study of syphilitic phenomena in general warrants the assumption that syphilis is a disease of extremely slow evolution; in other words, the syphilitic virus (or whatever the infective agent may be) undergoes in the body, as time advances, a transformation which endows it with the power of initiating in the organism structural changes, corresponding to more or less definite periods in the evolutionary cycle of the virus; the ultimate product of its activity being represented in the so-called parasyphilitic or, as I would prefer to designate them, ***terminal syphilitic*** affections. And of these the principal examples are met with in the

*Lancet*, June 13, 1903.

central nervous system; namely, locomotor ataxia and general paresis. Now if we accept this hypothesis as to the slow evolutionary nature of the syphilitic virus we must admit that changes characteristic of its terminal stage should, of necessity, differ from those of the preceding stage, just as to the changes of this, the tertiary, differ from those of the secondary and primary stages. The changes of the terminal stage being we consider as truly syphilitic as any other stage of the disease, in origin and nature as one.

The fact that anti-luetic medication is valueless in the treatment of tabes is one of the strongest arguments advanced against the syphilitic nature of this disease. We all know that the iodides and mercury are useful in the earlier stages of syphilis in so far as they remove subjective and objective evidence of the disease; we further know that there are many recognized syphilitic affections, especially in the so-called tertiary stage, that are not benefited particularly, if at all, by this line of treatment, and from the number of syphilitics who have received a thorough course of treatment but who later develop tabes we may justly infer that the iodides and mercury do not possess the curative qualities generally accredited to them, but instead their power is in the direction of removing the outward evidence of syphilis in its earlier stages rather than in affecting its cure; and this power is completely lost in the terminal stage (parasyphilitic) for reasons that are quite obvious; namely, changes in the character of the lesions. Of course I do not wish to be understood as saying that the so-called specific treatment of syphilis is never curative, for there is ample evidence to show that apparently in many instances it does as is claimed, but on the whole it is not the specific *par excellence* that syphilologists would have us believe, and its value as a criterion by which to judge the specificity of a disease is extremely uncertain. This is clearly expressed by no less an authority than Hutchinson, when he says "Those who think that the results of treatment by specifics may be relied upon as establishing the diagnosis may easily make great mistakes, syphilitic affections often resist treatment for a long time (I may add, even altogether), and on the other hand mercury and the iodides often effect the greatest possible good in cases which are not syphilitic." Any one who has watched the progression of the symptoms of syphilis, and especially in connection with the operation of remedies, must have realized a relationship which might be expressed as follows: Syphilis is manifested by a well-defined succession of stages or periods, with intervals of apparent submerged, or quiescent action of the virus; each period or stage of the disease becomes longer corresponding to the order of its sequence; the efficacy of treatment diminishes directly according to the progression of the stages.

It is true, as claimed, comparatively few syphilitics develop tabes, but I fail to see how this fact can in the least militate against the syphilitic nature of this disease. If this argument possesses any value in tending to demonstrate that tabes is not a syphilitic but a parasyphilitic affection, why do we admit, with similar evidence before us, that there is an alcoholic neuritis instead of a paralcoholic neuritis? Surely the occurrence of alcoholic neuritis is exceedingly rare compared with the number of individuals who habitually use alcohol to excess. Those who advance this argument evidently lose sight of the fact that tabes is but one terminal syphilitic affection, there are many others—as, for example, general paresis, which is about as frequent as tabes itself—and if we add these together we will find that there is not so striking a disproportion between primary and terminal syphilitic affections. There is, however, very naturally a disproportion, and this is as it should be when we consider that our organism is endowed with a defensive mechanism which enables it, in most instances, to engage in battle and defeat any agent which, when introduced into our body, is inimical to its well-being.

Occasionally in the case of syphilis (as in every other disease) the infecting agent is capable of holding its ground against our defensive mechanism, and in the case of syphilis is thus able to produce in a comparatively small percentage of cases tertiary symptoms, and in a still smaller percentage terminal symptoms. In this respect it is instructive to note that it is the exception rather than the rule to find patients suffering with tabes giving a history of a severe syphilitic infection. In fact, in most instances the primary and secondary manifestations are described as having been mild in type. But when we find tabes developing in from six to twenty years after such an infection, I believe it is a positive answer that the primary infection was not less virulent than is usual, but rather that the organism, in the first place, failed to react to the presence of the virus as it should, the virus thus being permitted to continue its evolutionary cycle practically unopposed.

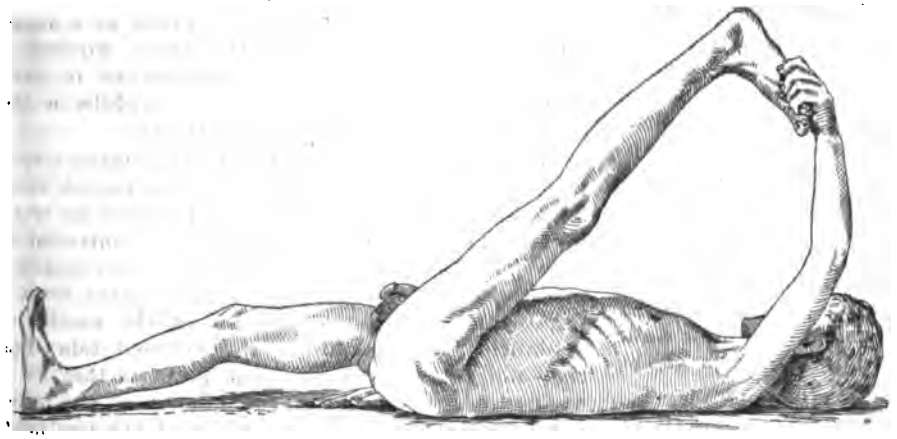
The rarity of tabes among certain races (Negroes, Chinese, etc.) accredited with being syphilitic I believe is to be accounted for, first, on the ground that since such races have by their mode of living acquired so unenviable a reputation, they for the very same reason have acquired a more perfect physiological method of combating the disease; and, second, such races are not to any great extent exposed to the enervating agencies that go hand in hand with higher civilization and which play indirectly so important a rôle in the causation of tabes.

The infrequency of tabes in prostitutes is pointed to as most convincing proof that tabes is not a syphilitic disease, and the very authorities who ask us to accept this tell us in the same breath that sexual excess, alcohol, and excesses in general are all capable of causing tabes. If this is so, it is very singular that there are not more prostitutes affected with tabes. For if there is a class of people in this world in which sexual excesses and general dissipation are inseparably associated it is in this class of unfortunate creatures. They may have been taught to protect themselves against syphilis, but they never can protect themselves against sexual excess and seldom do against alcoholic dissipation. If then the rarity of tabes in prostitutes can be pointed to as tending to show that tabes is not a syphilitic disease it should also be pointed to as constituting an unanswerable argument that tabes cannot be caused by sexual excess, alcohol, or dissipation in general. I believe, in part, an explanation of the rarity of tabes in this class of women, is, that possibly they are not syphilitic as often as we suppose. It is well known that tabes is much more frequent in men than in women. This has been accounted for on the ground that men are more exposed to syphilis and to those agencies reputed to be contributory in causing tabes than are women, but when we turn to prostitutes this reason does not seem to possess much value. So I believe we are justified in assuming that either women, as a class, are endowed with a more perfect immunity against terminal syphilitic sequelæ of the nervous system than are men, or that they are not syphilitic (including prostitutes) nearly so often as are men.

Alcohol, sexual excess, and the "strenuous life" occupy an important rôle in the etiology of tabes only in so far as they cause a depreciation of vitality in the neuron, which permits the poisons engendered by the luetic infection to attack the neuron with increased virulence.

The disease is commonest in the middle period of life—35 to 45 in men and 30 to 40 in women. It, however, occurs at times in persons much older and younger. Bramwell records a case in which the disease began in a man at the age of seventy-three years and Collins one at the age of sixty. When occurring under the age of twenty years the term juvenile is applied, or if much younger, during the first few years of life, infantile. The disease at this period is extremely uncommon, and is probably due to hereditary syphilis.

Among observers who have not devoted especial attention to the subject the question is often asked if injuries, especially of the spine, are not a cause of tabes, for patients not infrequently attribute their illness to this cause, and this they are especially liable to do if the injury, however slight, was sustained under conditions which suggest the possibility of remuneration if the case be carried to litigation. There are many reported cases of tabes seemingly due to trauma, but the number reported without a co-existing syphilitic history is exceedingly small, so that one is forced to the conclusion that the *rôle* (if any) assumed by trauma in the etiology of locomotor ataxia is similar to that of alcohol and other depressing agencies.



Showing rather extreme cases of muscular hypotonia in tabes dorsalis.

As the lesion of tabes is primarily one of the posterior columns of the cord or of the peripheral sensory neuron, it follows that the symptoms first presenting themselves should be those depending upon irritation in these tracts. This is what occurs, and in the vast majority of cases pain or paræsthesia, involving usually the legs, is complained of first. The paræsthesia which the patients most often describe as numbness, but which may be any perversion of sensation, is confined to a limited portion of one foot or leg, or may involve the body from the waist down, or more rarely is confined to portions higher up, as the hand or arm; when occurring around the waist it is often referred to as the girdle symptom. The pain may be shooting, lighting-like, or dull in character; it is usually intermittent, and seems often to be aggravated by damp weather. It is at this period that patients consult the family physician, and it is at this period that the diagnosis "rheumatism" is often made. I have rarely seen a patient with tabes who has not been under treatment for a considerable period of time for rheumatism, and this notwithstanding the fact that often many of the signs pathognomonic of the disease were already present.

Occasionally one of the earliest and most distressing symptoms is paroxysms of coughing or retching and vomiting with gastric pains and possibly diarrhœa, constituting respectively the laryngeal and gastric crises. In a limited number of cases diplopia will be the first symptom complained of. Disturbance of the urogenital system is usually an early sign, and may manifest itself in incontinence or retention of urine, or in some interference of the sexual function; as diminished desire, capacity, or complete impotency. The bowels are apt to be constipated. Any of these symptoms alone or in combination may continue for months or years without change when added to them will be some disturbance of locomotion, as difficulty in going up or down stairs, or when walking in the dark, or a tendency to fall, especially on turning corners, or as in the case of commuters when running to catch a train, a giving away at the knees is complained of, this being due to muscular hypotonia. The latter condition is well illustrated in the accompanying illustrations, taken from a patient in the clinic of Prof. Joseph Collins. It consists, in a diminution of the normal muscular resistance, which can be demonstrated by placing the limbs or body in positions that ordinarily are not possible in health. It is in reality the opposite of spasticity, which is characterized by an increased resistance to passive movements; while in muscular hypotonia there is a diminished resistance to passive movement. Muscular hypotonia is therefore often a valuable sign in early tabes.

As the disease advances the patient experiences difficulty in walking under any condition, and soon develops the gait and posture so characteristic of the disease; the eyes are kept on the ground, the body bent slightly forward, the legs lifted forcibly and the feet brought sharply to the ground, heels first. After several years in this condition, unless properly treated, the patient loses entirely the power of walking, becomes bed-ridden, where he may remain for many years, finally dying of some intercurrent disease.

When, therefore, a patient presents himself, complaining of any of the symptoms above enumerated, it is incumbent upon the consultant to institute so thorough an examination of his patient that the signs of tabes, if present, will be revealed. With that end in view the patient's entire clothing should be removed.

Note if there is any ataxia of station, so-called Romberg sign, consisting of swaying of the body when the eyes are closed and the feet in apposition. Observe if there is any ataxia of the upper or lower extremities; examine knee-jerks and Achilles jerks, the latter may be the first to disappear, and the former disappear early except in high tabes, or are only brought out slightly on reinforcement.

The pupils may be unequal in size, but are more apt to be equal and small, and in the early stage they may respond sluggishly to light, but later they lose this power, but usually continue to react to accommodation; the so-called Argyll-Robertson pupil.

Objective sensory disturbances are nearly always an early sign in tabes and may consist in a small area of complete or partial analgesia often found only on the outer side of the leg. There may be areas of anæsthesia, or the sensations may simply be delayed in transmission. Areas of hyperæsthesia are common, especially in the very early stages.

Probably the physical signs of tabes are presented for a considerable period of time prior to the development of symptoms that attract the patient's attention to any great extent. Therefore when the tabetic consults a physician because of paræsthesia, pain, loss of sexual desire, or other symptoms of similar significance, he is likely to have physical signs that are characteristic of the disease, and of these the most important are loss of the knee and Achilles jerks and the presence of the Argyll-Robertson pupil. But odd as it may seem there are cases in which these important signs are reversed. This is shown by the following history of a patient I saw recently.

X., American, age thirty-five years, single, occupation baker, was seen in Dr. Collins' clinic. Nothing of importance in family history, has been a very moderate beer drinker but an excessive smoker. He had never been seriously ill. Denies absolutely a venereal history. His present complaint dates from an attack of diarrhœa, vomiting, and abdominal pain which occurred seven months ago; he was confined to his bed for several weeks, and upon getting up he noticed a numb sensation around his waist, which rapidly extended to and involved both lower limbs. These symptoms continued for two months; then he began to experience difficulty in going up or down stairs; a giving away at the knees and a sensation as if carpet were interposed between the soles of his feet and shoes. Transient attacks of diplopia occurred at this time. During the past two months he has been gradually getting worse, he cannot walk well in the dark, and when walking in the street must keep his eyes on the ground.

On examination there was found slight ataxia of station and gait. His pupils were equal and responded promptly to light and accommodation and his knee and Achilles jerks were distinctly lively, as were his plantar reflexes, which were of the flexor type. Aside from quite pronounced hyperæsthesia over legs and lower portion of body there was no other objective sensory disturbance. Hypotonia could be demonstrated by the freedom with which the limbs could be moved in extreme positions. His bladder function was normal, but he is subject to attacks of abdominal pain and diarrhœa occurring possibly every month or so.

This case is unquestionably one of tabes, the lesion not as yet having progressed beyond an irritative stage, which accounts for the occurrence of paræsthesia, hyperæsthesia, and lively reflexes. It also serves to illustrate a case beginning with the gastric crisis. Such atypical cases are relatively rare, and the vast majority of tabetics may be said to conform to a fairly regular type, which admits readily of detection if one proceeds with the examination of the patient in a routine manner.

Many interesting signs and symptoms occur in the later stages of the disease, but we may pass them by, as our concern is with the importance of making the diagnosis early. Therefore only the most important initial manifestations of any diagnostic value have been brought forward.

We should at once become suspicious of tabes if a patient presents himself for examination giving a history of syphilis, the disease having been contracted six to twelve or more years before and complaining of paræsthesia or pains, especially in the legs, or of diplopia or any disturbance of the urogenital or gastrointestinal systems. No doubt one's suspicions will be more quickly aroused if the patient presented some difficulty in locomotion, but, as a rule, this sign does not belong to an early period of the disease. Tabes in its various stages is to be distinguished from chronic myelitis, multiple neuritis, spinal tumor, spinal syphilis, general paresis, Friedrich's ataxia, hysteria, and neurasthenia.

The prognosis in tabes depends largely upon the clinical type of the disease; but as regards cure it is practically hopeless, although under proper treatment and régime the patient may live anywhere from ten to thirty years, and his usefulness as a unit of society need not be particularly curtailed. In the so-called cervical tabes, which fortunately is quite rare, death is likely to occur early, owing to implication of important centers in the medulla.

When one considers the cause of tabes, its prophylaxis theoretically is easy; namely, the prevention of syphilis; but it is needless to say that the accomplishment of this ideal to any appreciable extent, is well-nigh impossible so long as the laity at large, even educated people and, perhaps, occasionally the physician, look upon syphilis as a disease whose worst features are the time required in effecting a cure and the inconvenience of treatment. Not the least danger of syphilis is this complacent disregard of its aftermath.

We find, too, that patients develop tabes after a thorough course of anti-syphilitic medication about as often as do those who have received no treatment. This latter statement is not intended to convey the idea, however, that anti-syphilitic medication is valueless in preventing tabes, for it is impossible to form an estimate of the number of syphilitics who would have developed tabes had they not taken treatment, the point is that one is by no means safe from the effects of the luetic poison, even though he has received the treatment recognized as "specific."

Syphilis having been contracted, our prophylaxis resolves itself into insisting that the patient submits to a thorough course of appropriate treatment; and further, we should impress upon him the necessity of leading a life free from those cares and excesses which are reputed to assist in the development of tabes.

When tabes has developed, the treatment consists in placing the patient under conditions that will guarantee him immunity from physical and mental strain and excesses of all kind. He should so far as possible guard against inducing leg weariness, as this tends to aggravate the disease. As general tonic agents fresh air and hydrotherapy are of service. For the ataxia, which is so distressing a symptom when the disease is well developed, the Fränkel movements are of great service, and if properly carried out the benefit derived is often very gratifying. Electricity is used very extensively in the treatment of this disease, but it practically does no good other than to maintain the nutrition of the muscles, but for this purpose it is inferior to massage, which is an excellent agent. The static spark and the high-frequency currents often seem to relieve the paræsthesia and pain. The use of electricity also gives

the patient confidence that something is being done for him, and in this way tends to mitigate distressing mental symptoms. The galvanic current is useful in some cases and should be applied with the positive pole over the chest and the negative along the spine every day, or every other day, and long enough to induce a hyperæmia. A current of from ten to fifteen milliamperes is sufficient, but as the patients are often wholly or partially anæsthetic, they will endure a much stronger current without complaining. This, however, should not be given them.

Drugs are of little, if any, service aside from their action as general tonics, and for this purpose strychnine, potassium iodide in small doses, and the organic preparations of iron are good. Nitrate of silver is seldom used now because the benefit derived, if any, is offset by the discoloration it produces in the skin. As has been said before anti-syphilitic medication *per se* is valueless in tabes; in fact, it is contraindicated, as it is likely to disturb digestion and lower the resistive power of the individual. If the symptoms of tabes, however, should develop within five years after luetic infection, or if there is any evidence of exudative syphilis in the individual, we should place the patient upon anti-syphilitic medication, as we may be possibly dealing with a spinal lues, or, in other words, tertiary syphilis, that resembles tabes or terminal syphilis and to which the term pseudotabes is applied.

The current theories of the pathogenesis of tabes are so well known that nothing is gained by reviewing them here; in fact, none of the hypotheses tending to explain the origin and course of the lesions are entirely satisfactory. A recent theory, however, by Marie and Guillian* bids fair to become a very important one in the pathogenesis of tabes, for it directs attention to disturbances in the lymphatic system of the spinal cord. Changes in the spinal lymphatics as a remote or direct consequence of syphilitic infection seems to have been considerably neglected by patho-anatomists compared with the enormous amount of work upon other structures of the cord, and Marie and Guillian bring a very timely and possibly the most satisfactory explanation of the lesions.

These authors have studied especially the lymphatic structure of the spinal cord and membranes and conclude on patho-anatomical grounds that the posterior division of the spinal pia communicates very little or not at all, with the pia of the lateral and anterior regions. They are inclined to view the lymphatics of the posterior spinal pia as an independent system.

The authors then discuss the lymphatics of the spinal cord. These are but little known, but by experimental injections of the substance of the cord by colored liquids; the pathway chosen in injections of bacteria; by the determinate course of extravasations of blood in hematomyelia; and also by the study of a very early case of tabes by the method of Marchi, in which the distribution of the black Marchi droplets remained confined to the posterior column lymphatics, the authors conclude that the lymphatics of the posterior columns constitute a distinct and autonomous system.

The writers believing, then, that both the posterior columns of the cord, together with the posterior spinal pia, have a separate system of lymphatics, go a step further, and conclude that the whole posterior system of the spinal cord, namely the posterior roots, the posterior segment of the pia, the intramedullary continuation of the posterior roots—the columns of Burdach and Goll—constituting a more or less compact unified physiological system, has also its accompanying distinct, separate and dependent lymphatic system. In brief, this unified anatomical and physiological system has in its nutritive and excretory functions an equally parallel and independent system of lymphatics—independent in the sense of being apart from the general spinal lymphatic system. Thus in the two systems, each complete and more or less independent, the activities of the one work hand and hand with the other.

It remains now in view of this discovery—if such it proves to be—of the separate character of the lymphatics of the posterior system, to inquire into the origin of the tabetic process. The authors think the question has been simplified by their theory of infection of the posterior lymphatic system. In fine, they regard the tabetic process not as a lesion of the posterior root axones nor indeed of the neuroglia, but simply as a syphilitic disease of the posterior lymphatic system; a syphilitic lymphangitis of the posterior columns, roots and pia. The writers do not state distinctly the character of this syphilitic lymphangitis, but it is to be presumed that the process is one inducing adhesions or occlusions of the lymphatic crevices as the primary starting point of the tabetic lesions. Nor do the authors enter into the question of the parasyphilitic, or, as I have preferred to designate it, terminal syphilitic rôle in the production of this lymphangitis.

The weight of evidence, however, in our present contemplation of the syphilitic induction of several chronic neural lesions would be in favor of the late or terminal action of the syphilitic poison. This seems probable, for the tabetic lesion, granted that it is a primary occlusion of the lymphatic spaces, never shows the structural features of an acute and richly cellular change in the cord, like that in acute and subacute syphilis, which we may regard as an active and relatively early expression of the syphilitic virus. On the contrary, the changes in tabes are exceedingly slow and gradual; the progression at times is indeed by infinitesimal increments; the new tissue in the cord is never luxuriant in cells, but consists of slow accretions of neuroglia, with corresponding diminution of nerve fibers which we may justly regard as typical of terminal syphilitic affections of the nervous system.

Certainly the views of the French authors open up new fields of survey of the origin and course of tabes, and incite renewed interest in the morbid anatomy of this disease. While the hypothesis of Marie and Guillain does not explain the discrimination and selection of the posterior system of the cord by the syphilitic virus, it does explain why when this region has been infected the pathological changes set up therein do not as a rule exceed its bounds.

I am very much indebted to Dr. Joseph Collins, from whose Clinic this paper emanates, for the use of his rich material on this subject.

**Cicatricial Deformities in the Respiratory Tract Due to Causes Other Than Syphilis and Traumatism.**—From a collective investigation based on 300 replies sent to a circular letter issued by G. H. Makuen, he finds that this number of observers have seen 449 cases of cicatricial deformities in the respiratory tract that appear not to be due to syphilis or traumatism, and that 16 per cent. of these were caused by diphtheria, 8 per cent. by scarlatina, 3 per cent. by lupus, 1.6 per cent. by tuberculosis, 1.5 per cent. by scarlet fever and diphtheria combined, 1.1 per cent. by typhoid fever, and 0.5 per cent. by measles. Other causes given in the nostrils are membranous rhinitis, catarrhal erosion, smallpox, scleroma, septal abscess, erysipelas, and pemphigus.—*The Laryngoscope.*

# TRAUMATIC SEPARATIONS OF THE LOWER EPIPHYSIS OF THE HUMERUS AND THEIR TREATMENT BY THE EXTENDED POSITION. WITH REPORT OF TWO CASES.*

By GILBERT GEOFFREY COTTAM, M.D.,
ROCK RAPIDS, IOWA.

UNDER the caption of "Problems of Clinical Anatomy,"[1] Thomas Dwight, the Harvard anatomist, recently read a paper, the purpose of which was to show how inexact a science anatomy is, notwithstanding the traditional belief to the contrary. His argument was based upon the wide variation met with in the different anatomical structures, and his views will be concurred in by all whose knowledge of anatomy has been derived from a considerable experience in the dead-room.

The resultant difficulty of determining upon a standard for descriptive purposes has led to no little confusion, which has been greatly augmented by the lack of a standard of nomenclature.

To any one writing of the elbow-joint this is especially apparent, there being a singular want of uniformity among the existing descriptions of the lower end of the humerus.

The most satisfactory is that of Krause,[2] based upon developmental grounds, defining the lower end of the humerus as comprising the internal and external epicondyles, the trochlea, the capitellum, and the coronoid and olecranon fossæ.

In considering the subject of epiphyseal separations it is desirable that we have a general understanding of the postnatal development of the part involved, bearing in mind that this, too, is subject to a wide degree of variation.

In this instance there are four ossific centers, *i.e.* one each for the internal and external epicondyles, the trochlea, and the capitellum. That for the capitellum appears about the third year, for the internal epicondyle at about the fifth year, that for the trochlea at about the twelfth year, and that for the external epicondyle at about the fourteenth year. About the fifteenth year the trochlear and capitellar portions fuse together, being joined a little later by the external epicondyle. These three units constitute the true lower epiphysis of the humerus, and undergo osseous fusion with the shaft at about the seventeenth year. The internal epicondyle remains separate for several years longer, ultimately becoming joined to the shaft direct.

Of especial clinical importance is the extent to which the epiphysis participates in the formation of the olecranon fossa. At birth it constitutes the lower one-fourth, but as growth proceeds it encroaches upon the fossa less and less until, at the twelfth year, it forms but the lower margin of the cavity. In separations of the epiphysis in early childhood, then, followed by exuberant callus production in the reparative process the olecranon fossa will be more or less filled up, with consequent limitation of extension of the forearm. This, it will be seen, is one of the arguments in favor of the extended position in the management of these injuries.

The diagnosis of separation of the lower epiphysis of the humerus, indeed of all elbow-joint injuries in childhood, is often a matter of great difficulty. As guiding points we have the history of the accident, the age of the patient and the evident location of the injury very close to the elbow. The symptoms are: (1) early and extensive swelling—which also serves to further obscure the diagnosis; (2) preternatural mobility; (3) deformity, which is readily overcome, but easily reproduced; (4) muffled crepitus—a very suggestive term first used by Poland; (5) shortening of arm; (6) limitation of active movements by pain; (7) ecchymosis about the elbow.

It is particularly essential to differentiate between this lesion and backward dislocation of the ulna. In the latter we may have early and extensive swelling, and very likely limitation of active movements and the ecchymosis of the parts about the elbow, but instead of abnormal mobility there will be fixation, the deformity, instead of being readily overcome and easily reproduced, is difficult to overcome, and has no tendency to relapse, and there is no crepitus or shortening of the arm. E. Albert of Vienna[3] furnishes an additional aid to the differentiation of the two lesions. He says "It is evident that the forearm, in company with the lower fragment, can be displaced backward. The olecranon is then prominent posteriorly, and is displaced upward; the radius has left its normal position, and the forearm is shortened. The symptom-complex resembles that produced by a dislocation. Palpation discloses the tip of the olecranon above a line drawn between the epicondyles, and as the relative position of the olecranon to the epicondyles is altered, we are led to assume that a dislocation exists. But, on testing flexion beyond a right angle, no resistance is encountered. This seeming incongruity—viz., relation of the anatomical points, as in dislocation—combined with unimpaired flexion, is characteristic of epiphyseal separation."

*Treatment.*—A casual survey of the literature shows that writers of the present day are far from being agreed as to the proper angle at which the arm and forearm should be retained after reposition of the fragment. Appended are a few opinions:

*Jonathan Hutchinson, Jr.*. The muscles retain the lower fragment in such a position that the joint itself is always flexed; and, therefore, if we straighten the arm there will be backward displacement.[4]

*Poland* is of the opinion that epiphyseal separation of the lower end of the humerus is best treated by the flexed (rectangular) position, however strongly the position of full extension may be urged in the treatment of some of the other forms of injury to the elbow-joint.[5]

*H. R. Wharton* advocates placing the forearm at an obtuse angle or at an angle of less than 90° with the arm.[6]

*L. S. Pilcher:* "By placing the forearm in the extended position the humero-ulnar angle can be kept under control; but as some anterior rotation of a condyloid fragment is inevitable . . . the probabilities of late functional impairment of the joint are increased, and in case of ankylosis the position of the joint is the most objectionable that could be produced." He therefore advocates the H. L. Smith position of acute flexion.[7]

*L. A. Stimson and E. L. Keyes, Jr.:* Advise immobilization with the elbow flexed at right angle and the forearm in semi-pronation. Incidentally they also recommend weight traction.[8]

*C. L. Scudder* says: "Separation of the lower epiphysis of the humerus will be best treated in the right angle position."[9]

*William Barton Hopkins* believes in the right-angled or obtuse-angled position, with preference for the former.[10]

*Helferich* "Splint dressing in the most appropriate position, sometimes almost or fully extended, sometimes with flexion at the elbow."[11]

I have also at hand a very practical paper entitled "Treatment of Fractures and Injuries to the Elbow Joint," by A. J. Gillette and J. B. Brimhall of St. Paul,[12] in which an uncompromising position in favor of the extended position in all injuries and diseases requiring immobilization of the elbow, is taken, with the support of thirty cases, twenty-eight of which

*Read at the thirtieth semi-annual meeting of the Southwestern Minnesota Medical Society, held in Windom, Minn., on July 9, 1903.

were followed by perfect functional results, the remaining two being fair. One only of the cases seems, however, to have been a separation of the lower epiphysis of the humerus.

It is not possible for me in the limits of this paper to enter into all the arguments for and against each method of managing this troublesome class of cases, nor would I be justified in drawing conclusions from the two cases treated by the position which seems to promise the best results in the future. The ground already traversed in this paper is merely to draw attention to and invite discussion upon a branch of surgical art which has been grossly neglected in the past and which has been productive of very poor results. It is only by the agitation of such matters that we can expect to obtain improvement.

My two cases are as follows:

Case I.—April 4, 1903, H. a little girl aged six, fell while playing in a hay-loft and injured her left elbow. I saw the case about three hours after the accident and found very marked swelling, ecchymosis and abnormal mobility. There was muffled crepitus and backward displacement of the olecranon, with no interference with flexion. Diagnosis: traumatic separation of the lower epiphysis of the humerus. On account of the great swelling I did not apply a cast at this time, but used a straight padded wooden splint, extending from the fingers to the axilla, the forearm being supinated. This was done after perfect reduction of the fragment, which was very easily accomplished without anæsthesia. On April 11, one week afterward, I substituted a plaster-of-paris cast and left it on until May 9, a period of five weeks, when it was removed and the joint found to be normally movable, followed later by perfect muscular control.

Case II.—April 22, 1903, L. H., a little boy, aged four, was thrown from a buggy, falling heavily upon his left arm. Seeing him shortly afterward, I found him suffering severely, but with little swelling of the elbow. Otherwise, under chloroform anæsthesia, the symptoms were identical with those of the other case. After accurate reduction of the deformity I immediately applied a plaster cast, from the fingers to the axilla, over flannel, the arm being fully extended and in the supine position, with preservation of the carrying angle. The cast was not disturbed until exactly one month after the accident, when I removed it and found the joint-function as unimpaired as in the case just described.

These being the only two cases of elbow-joint injury which I have treated without some degree of loss of function I may, perhaps, be pardoned for feeling encouraged to continue the use of the extended position in the future, despite the weight of authority against it.

## EMULSION-ALBUMINURIA.

By ISADOR H. CORIAT, M.D.,
WORCESTER INSANE HOSPITAL, WORCESTER, MASS.

Under the name of emulsion-albuminuria, Cramer has recently described[1] a rare and interesting condition in which the urine passed shortly before death had a milky appearance. According to the author, this arose, not from any admixture of fat, as occurs in chyluria or lipuria, but from the presence of some proteid substance in an unusual physical state. The condition was first found to occur in two cases of puerperal eclampsia with death from coma, and had been reported a year previously.[2] The third case was that of a woman, aged fifty-eight years, who had been a sufferer from rheumatism for some time, and was brought to the hospital in a state of great anxiety and fear and complaining of headache and disturbances of vision. She rapidly developed dyspnœa and œdema, the complexion became livid, the pulse 126, and there was a temperature of 37.6° C. The urine was acid, small in amount, greatly concentrated, and contained an abundance of urates. There was no improvement under diuretics, she developed amaurosis, became stupid, and rapidly went into a condition of coma with cyanosis and tracheal râles. Two days before death she passed 300 c.c. of a milky urine, which was examined by A. Schmidt. Neither warming, nor the addition of an acid, filtration, nor centrifugalizing removed the milky appearance. Under the microscope innumerable minute globules could be detected, but ether extracted no fat and the osmic acid reaction was negative. A few drops of acetic acid or of potassium hydrate reduced the milky appearance to one of opalescence, and this change was hastened on heating. Water added to great excess produced a similar result. On boiling, a copious precipitate was obtained with a disappearance of the opacity. Artificial peptic digestion cleared the urine, hydrochloric acid alone did not. The examination of the sediment showed a large number of uric acid crystals. After heating with 1 per cent. hydrochloric acid for an hour, there was obtained a crystalline deposit, which was identified as allantoin. At this time the author stated that no other instance had been reported in the literature of a milky urine due to native proteids. Since his publication, however, I have been able to add a fourth case to the reported series. As the condition under which this peculiar state of urinary albumin may occur is but little known, the clinical history of my case, the urinary examinations and the post-mortem findings are given rather fully.

The patient, a man forty-seven years of age, a painter by occupation, was admitted to the Cambridge Hospital on October 25, 1901. The records state that he had been a sufferer from occasional attacks of lead colic for the last year, had used alcohol freely and was frequently intoxicated. The day before admission he had several general epileptiform convulsions and was brought to the hospital in an unconscious condition. There the convulsive seizures continued and an examination of the urine showed the following: Color smoky, reaction alkaline, specific gravity 1,021, albumin ½ per cent., sugar absent; sediment —some abnormal blood, a few leucocytes, many triple phosphate crystals, a few epithelial and finely granular casts. He soon became very noisy and showed a rapidly increasing delirium and so was committed to the Worcester Insane Hospital on October 25, 1901. Here the delirious condition continued with many hallucinations and illusions, much confusion, and great fear. He was very

restless and slept only with hypnotics and sedatives. The temperature varied from 99° to 103° F. The physical examination showed a poorly nourished and emaciated man, lips and mouth dry, teeth covered with sordes. The knee-jerks were exaggerated and there was a tremor of the hands and tongue. The left elbow-joint was ankylosed and considerable arteriosclerosis was present. After he had been in the hospital for four days there was a sudden rise of temperature and increased short and jerky respirations. The examination of the chest showed harsh breathing on both sides in front, and over the lower lobe there was a distinct pleuritic friction sound. No dulness could be made out. He passed a small quantity of clotted blood mixed with fæces.

On October 30 dulness had developed over the right lower lobe, and on auscultation there could be heard hard crackling sounds on both inspiration and expiration. The respirations were rapid and jerky, and he complained of severe pain on the right side. Temperature 101°, pulse 90 and weak. Abdomen tense, with some diffuse tenderness on the right side. The bowels were considerably constipated and an enema produced a movement of yellowish fecal matter in which there were several blood clots. He did not pass over a pint of urine all day and only a portion of this was, unfortunately, preserved for analysis. It was milky white in color and opaque. The details of the analysis will be given further on. The blood examination showed the following: Hæmoglobin, 65 per cent.; red cells, 4,875,000; leucocytes, 13,335; relation of white to red cells, 1:265; differential count (600 cells)—small mononuclear, 2.3 per cent.; large mononuclear, 0.5 per cent.; polymorphonuclear neutrophiles, 97 per cent.; eosinophiles, 0.2 per cent.; there was some poikilocytosis; the red cells were rather pale.

The urine on October 31 had lost its milky color, and analysis showed: Color, light amber with heavy, stringy sediment; reaction, acid; chlorides, very small in amount; albumin, a large trace; sediment, a few granular casts.

The examination of the chest on the same day showed tubular breathing over a small area in the right lower lobe, but over the scapula the breath sounds were faint. Temperature 100°, respiration 36. The patient was very restless. The bowels moved freely. During the day he passed but little urine and diuretics had no effect. The next day the fever was lower, but the respirations were 40 and the pulse 130 and very weak. There were large bubbling râles everywhere. The patient was constantly coughing and tracheal râles accompanied each respiration. There was dulness over the right lower and middle lobe and over the left lower lobe. He grew weaker, rapidly failed, became cyanotic, and died at 7.45 P.M.

The autopsy was performed fifteen hours after death and the summary of the findings is as follows: Œdema of left lung. Infarcts of right lower lobe. Right-sided pleurisy with a serofibrinous effusion. Residua of pneumonia of left lower and upper lobes. Cardiac hypertrophy, moderate atheroma. Double acute parenchymatous nephritis. Tumor of right cerebellum. Ankylosis of both elbows. There was an injected area in the mucous membrane of the cæcum, but no ulcers, bleeding points, or destruction of tissue were found in any part of the intestine. The weight of the left kidney was 80 grams, that of the right 105 grams. The capsule stripped easily, but left a very granular red surface behind, from which projected a large number of gray nodules, ½ to 1 mm. in diameter. Many of these were confluent and some of these were cheesy and some calcareous in nature. The cortex was 1.5 mm. in thickness, and the pyramids were very indistinctly outlined. Microscopically the vessels were thickened, and there was great destruction and desquamation of the lining epithelium of all the tubules with cloudy swelling. No casts could be seen.

The chief interest is attached to the urine which was passed three days before death, and which had the following characteristics: The amount was small, about 100 c.c. It was milky white and opaque in color, resembling that seen in chyluria. the reaction was acid, the specific gravity 1,012, sugar was absent and indican diminished. Microscopically there were found a few granular casts and some pus cells and uric-acid crystals. Fat globules were absent, and outside of the formed elements there was a homogeneous milky appearance even under the highest power of the microscope. The osmic acid test was negative. Neither warming, filtration, nor the addition of nitric acid cleared the urine. The opalescence did not disappear on long standing or on centrifugalizing. On heating there was some coagulation and the urine partially cleared, to become completely clear with an increase of the coagulum on the addition of a few drops of acetic acid. With Heller's test, it becomes more densely white at the point of contact. On the addition of sodium hydrate it nearly cleared up, but some opalescence remained; there was, however, a complete return of the milky appearance on the addition of nitric acid in sufficient amount to cause an acid reaction. The addition of water also reduced the milky appearance to one of opalescence. On shaking with ether there was only a partial clearing, and then the tests for albumin were easily seen. When the ethereal solution was evaporated, there remained an almost colorless residue with the odor of burnt molasses, which did not reduce Fehling's solution, gave a doubtful reaction with osmic acid and Nylander's test, while the acrolein test was negative. There was no formation of an osazone with phenylhydrazin and sodium acetate. It is to be regretted that so small an amount of urine was passed, as on the next day it had lost its milky appearance and regained its normal amber color, so that further investigation was impossible.

In all three of Cramer's cases death ensued in coma. Two of the cases were of puerperal eclampsia, the third patient suffered from some profound cardiac disorder associated with circulatory disturbances and oliguria. My case was one of alcoholic delirium with a coincident acute parenchymatous nephritis. There was also anxiety, fear, cyanosis, and the elimination of very small amounts of urine. In all four the urine assumed its peculiar milky appearance only a few days before death. This was clearly differentiated from chyluria or lipuria. The fat which occurs in the terminal stage of an acute nephritis is not to be considered, as it is eliminated in too small quantities to have any effect on the color of the urine, and can only be distinguished microscopically, either free or in the formed organic elements.

In my case the negative osmic acid reaction and the negative acrolein test afforded positive proof of the absence of neutral fat. All the proteid reactions were present.

We are undoubtedly dealing here with a rare, and hitherto undescribed form of albuminuria, in which the proteid exists, not in simple solution, but in an emulsion or rather a peculiar, colloidal physical state. The size of the proteid particles

held in suspension was so small that neither repeated filtration nor long-continued centrifugalizing could remove them from the solution. It is analogous to some of the other rare forms of urinary proteid, such as Noël-Paton's crystalline globulin, or Gutterink and de Graff's crystalline albumose.

This so-called emulsion albuminuria closely resembles the colloidal solutions (sols) of metals, in which, by electrical pulverization, such metals as platinum, iridium, or silver, becomes a mechanical suspension of exceedingly fine particles of the given metal in water or other fluid. And, indeed, since all proteids belong to the class of substances known as colloids, it is easily conceivable how such a substance could go into colloidal solution or suspension, resembling an emulsion, rather than dissolve and have the ordinary characteristics of a solid dissolved in a liquid.

Since then, there exists a physical state of urinary albumin apart and distinct from the ordinary one, our conception of albuminuria must be widened. We must be on the lookout for the more rare physical forms under which albumin may make its appearance in various pathological conditions, especially in the terminal stages of renal disorders.

# REPORT OF A NEEDLE IN THE PROSTATIC URETHRA.

By B. B. FOSTER, M.D.,
PORTLAND, ME.

April 27, 1897, Mr. J. M. called upon me at my office complaining of a great deal of pain immediately after urinating. The pain was excruciating and continued for some time. He had been for a short time under the care of a physican of this city who had informed him that he had gonorrhœa. Upon examination of the genitals I discovered a very slight urethral discharge, rather more of a mucous than of a purulent character. There was no swelling about the glands, and little, if any, tenderness about the urethra except at the posterior portion. From the symptoms presented I was satisfied that it was not a case of specific urethritis, and at my suggestion Mr. M. allowed me to introduce a sound into the bladder. As a result of this examination I felt very sure that there was a foreign substance either in the deep urethra or bladder. I so informed the patient and advised him that he should go to the Eye and Ear Infirmary for more thorough examination, and for an operation if such should be deemed advisable. In accordance with my advice, Mr. M. went to the infirmary April 30, 1897, where he was etherized with the understanding that any operation which promised him relief from his condition should be performed. There were several physicians present on this occasion, and all were invited to manipulate the sound for the purpose of seeing if they could detect a foreign body. As a result of this, out of the number present only two were able to convince themselves that they could detect anything of a foreign nature either in the deep urethra or bladder, consequently it was advised that no operation looking into the opening of the bladder should be performed, but as the patient had a very long and rather tight prepuce and a narrow, close meatus, it was thought that possibly the difficulty was reflex in its character, and that by performing circumcision and meatotomy he might be relieved. In accordance with this advice the operation for circumcision and enlargement of the meatus was done, and at the same time the bladder being thoroughly irrigated, after which the patient was placed in bed, kept very quiet and on a low diet. After this he was exceedingly comfortable, and his painful symptoms previously mentioned disappeared. May 18, 1897, he left the infirmary considering himself well, but in a very few days his former painful symptoms began to present themselves again, and on May 24, 1897, Mr. M. again entered the infirmary. On June 2, 1897, the patient was again etherized, and a careful examination being made, several of the physicians present felt sure that they found slight evidence of a foreign body which was supposed to be in the bladder. This being the case, all were agreed that it was advisable to enter the bladder, and median lithotomy was performed. The bladder was readily reached and the finger introduced, but I was entirely unable to detect any foreign body or any unusual irregularity of the bladder walls. Being unable to find any foreign material, it was decided to establish thorough drainage through the perineal opening with careful irrigation of the bladder each day. Mr. M. made a very rapid and uneventful recovery from this operation, and on June 29, 1897, a period of about thirty-six days, left the infirmary again considering himself perfectly well, not having had any pain or distress for some time, and the water having passed through the natural channel for a period of about two weeks. Mr. M. had only been from the infirmary a few days when he began to suffer as formerly. On July 1, 1897, he again entered the infirmary suffering with much the same line of symptoms as heretofore. This time he was placed in bed, kept perfectly quiet, the bladder thoroughly irrigated with boric solution, and at the end of nine days he again considered himself perfectly well and was discharged. For some time there was little heard from our friend except an occasional visit at the office to let me know that he was quite well and able to work every day, but unfortunately this condition came to an end September 29, 1897, when our patient put in an appearance at the infirmary with all of his old symptoms even worse than before. Again he was etherized and a thorough examination made. At this examination, as at the former, the majority of the gentlemen present convinced themselves of the presence of some foreign body which was supposed to be located in the bladder or possibly at the membranous portion of the urethra. After a careful consideration of the case with the other gentlemen present it was decided that I should be authorized to open the bladder by the suprapubic root. The operation was performed in the usual manner, the bladder was easily reached and entered, but notwithstanding a very thorough investigation of its interior, nothing of a foreign nature could be detected. This being the case, I had the patient drawn down to the edge of the table, placed in the lithotomy position and again made the median section, thus making free communication through the bladder. Still I was unable for some time to detect anything of a foreign nature. At this juncture I had the sound passed into the urethra and I was able to feel a foreign substance which seemed to be located at the junction of the membranous with the prostatic urethra. Carrying my finger in at the median opening, and pushing it down to the floor of the urethra, I detected with my nail a substance which was of a metallic nature. It was located just anterior to the prostatic gland, diagonally across the perineal tissues just impinging upon the floor of the urethra; on introducing a pair of

forceps and seizing the substance, I was somewhat surprised to bring to the light of day an ordinary button needle two inches in length, bearing in its eye a double thread of about the same length. The patient made a very fine recovery and was discharged from the infirmary November 13, 1897, a period of forty-five days after the last operation, this time perfectly well. Notwithstanding the bladder had been three times opened its capacity is good, and at the present time Mr. M. is in perfect health, able to retain his urine for a period of five to eight hours, and has no pain or unpleasant indications of any kind.

One will naturally ask how the foreign body reached this portion of the physical economy. In answer to this question I am only able to say that the patient claimed in the first place when he saw the foreign body which had been removed, that on the previous June he had been sewing a button to his trousers, and after securing it attempted to break the thread which he found to be very strong, and so he took up the trousers and bit off the thread. When he did this the needle and thread flew out of his fingers and went down his throat. He had never mentioned the fact of having swallowed any needle previous to its having been discovered. Shortly after the operation one of the surgeons who was present on visiting this gentleman in the infirmary asked him how he could explain the needle being there, and upon being told the above story the physician, in language more forcible than eloquent, informed him that he (the physician) thought he lied and that he believed he had pushed it into the urethra. Upon this suggestion for a time the patient was inclined to admit that such was the case, but soon after he returned to his former story. If he swallowed it, it must have worked down through the whole course of the intestinal canal and passed out through the rectal walls into the tissue where it was found. If it was introduced directly, this man having suffered so much, you would naturally suppose that he would have made mention of the fact. It is also pretty hard to explain how a foreign body of such magnitude, having been put into the urethra, could have passed out through the same into the locality where it was found. The above are the two stories told with reference to the introduction of the foreign body. You can select for yourself.

I wish, in closing this report, to thank all the medical men who were so kind as to consult with me in the case, and particularly Drs. N. M. Marshall, W. C. Cousins, and C. W. Foster for their very valuable assistance in the operations.

## A CASE OF LEAD OSTEOPERIOSTITIS.

By W. MOSER, M.D.,
PHYSICIAN TO THE GERMAN HOSPITAL, BROOKLYN, N. Y.

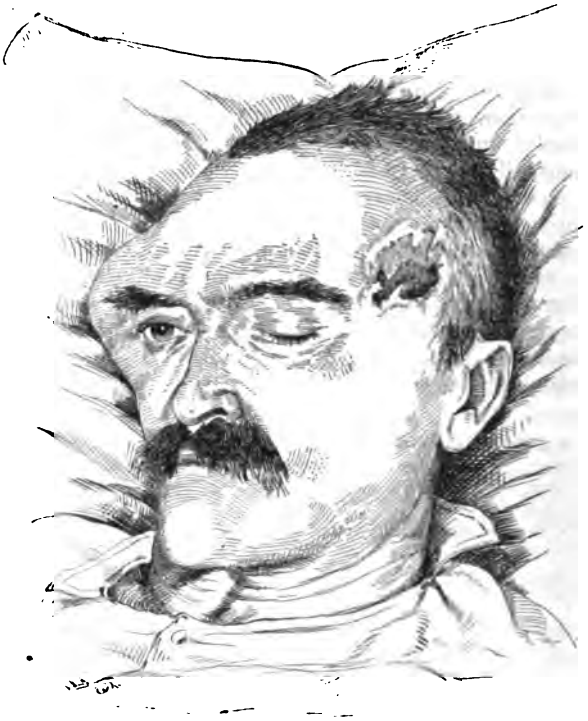
THE patient who has been engaged in lead works for many years exhibits a rather unusual manifestation of the awful ravages of chronic plumbism. The condition in question consists in an inflammation of bone and periosteum, with the formation of very large masses in the temporal region of both sides. These masses are somewhat soft and fluctuating to the touch, as though filled with pus, and the skin is reddened. The masses, however, are devoid of pus, but consist on the left side of granular cheesy, material, and on the right of a more firm, fibrous structure. They remind one of syphilitic osteoperiostitis, which they are not. The nodes are not especially painful at night, which so frequently characterize specific osteoperiostitis.

The illustration shows a node on the right side, and a wound on the left, being the remains of the extirpated node.

The node on the right side was merely incised, since it was too firm to be scooped out, as was the case on the left side. The incision was simply closed without a diminution in the size of the growth.

The patient's left arm is completely paralyzed, and the left eye shows ptosis.

He is in a state of chronic delirium (lead encephalopathy), having hallucinations of varied forms, as, for instance, he has seen his room filled with



fighting soldiers, etc. The patient was under my care for months before being transferred to St. Catherine's Hospital, and suffered intensely with arthralgia. Long before he came under my care he suffered from attacks of lead colic. In exceptional instances nodes occur over tendons in chronic plumbism, looking like a ganglion, and sometimes are confounded with this condition, or with gouty or rheumatic nodes. I am indebted to Dr. Jos. Samenfeld for the photograph and to Drs. Flynn and Jennings for details of the case while in the hospital.

The administration of iodide of potassium in these advanced cases seems to me to be worse than useless.

## ABDOMINAL PAIN IN PNEUMONIA.

By CHARLES S. GRABIN, M.D.,
BEBMER, NEB.

THE manifestation of abdominal pain in pneumonia without intestinal complication has been recorded several times of late. In April, 1903, I was called to see a child, who was supposed to be suffering from some intestinal trouble, the little one complaining of severe and persistent pain in the abdomen. The history and close examination revealed no abdominal trouble. Bowels about normal; pulse 130, temperature 103.5° in the axilla, respirations 40. There was marked flushing of the face, the breathing was puerile in character, and upon percussion marked consolidation of the right lower lobe was found. Complete recovery took place in a few days. My conclusion is that in these cases the pain is purely reflex. When we once consider the nerve supply of the lungs and stomach and the various distributions of the pneumogastric, the explanation of this occurrence is quite possible.

## THE THROAT AFFECTION OF THE GERMAN EMPEROR.

THE extirpation of what is officially called a polypus from the left vocal cord of the Emperor of Germany, although a very trivial operation in itself, carries with it a great deal of significance regarding the possibility of a speedy and absolute cure of the disease. In fact, the whole question turns upon the prognosis of the case. So far the reports are favorable, and the microscope has declared the growth to be myxomatous in character and free from any evidences of malignancy.

The operation was performed by means of the laryngeal snare, the bed of the wound having been treated by galvanocautery. From all accounts the tumor was evidently single in character and pedunculated, admitting of easy removal. Allowing this to be the case, the necessity for repeated and supplementary operations is obviated, and much dangerous irritation of the diseased parts will be prevented. This is an item of no small moment when the well-known malignant tendency of similarly situated laryngeal growths is taken into account.

More important than this is the consideration of the influence of heredity in determining the ultimate outlook for the distinguished patient. In nearly 25 per cent. of the reported cases of laryngeal cancer one or other of the parents of the victims died of the disease. In the case of the Kaiser, both his father and mother were afflicted with malignant disease, as also his uncle. His father lived but little over a year after throat symptoms were developed, and his mother died in the third year of a cancerous affection of the breast. From the side of heredity his prospects are certainly not very strongly guaranteed against the possible malignant development of what now appears to be only an innocent intralaryngeal trouble.

Nor can the early microscopical examinations always be considered the absolute tests of safety of opinion. It certainly was not so in the case of the late Crown Prince of Germany, as no less an authority than Virchow declared at the time when the first operation was performed on that royal personage, that the disease was entirely devoid of any cancerous tendency, and yet within two months afterward that distinguished authority was shown to have been mistaken.

All this shows that so long as any portion of any superfluous epithelial growth remains in a person of susceptible age, and especially if such an excrescence be subject to more or less continuous irritation, no one can be absolutely safe against malignant degeneration. Thus it is always a very important question whether or not the disease is thoroughly eradicated at the first operation, and also whether or not the wound heals in the shortest possible time.

It is generally admitted that in proportion to the early and complete fulfilment of these conditions is the tendency to recurrence reduced.

When such a course is impossible the microscopical examination of the merely superficial portions of the tumor are not always trustworthy as indicating immunity from future trouble, as not infrequently the removed parts may present healthy tissue elements, while the base may show distinctly cancerous changes. Obviously, then, the main consideration is to leave only absolutely healthy tissue in the bed of the wound. This has evidently been the fulfilled purpose in the Emperor's case, and the prognosis has at present all the desired hopefulness of a thoroughly successful operation.

In any event, months of time must elapse, even under most favorable conditions, before all anxiety can be allayed regarding a possible recurrence of the excrescence. In the meanwhile it will be necessary to keep a strict and constant watch for any unfavorable symptoms.

## THE REPUTED INCREASE OF THE DRUG HABIT.

IT has been publicly stated on many occasions of late, that the habit of drug-taking has largely increased in all civilized countries, and that in the United States this increase has been especially marked. Indeed, the subject has attracted attention from almost every quarter and has become a burning question of the day. It is probable, however, that while there may have been within recent years a very decided increase in the number of those addicted to the drug habit, yet it must be confessed that many of the accounts given bear upon them the ear-marks of exaggeration. Nevertheless, the evidence offered would seem to be quite sufficient to prove that drug-taking is indulged in to a very large extent, and that the situation in this respect is a serious one. Perhaps in this country—although it would be impossible to make an absolutely positive statement on the matter—cocaine is almost as widely resorted to for its narcotizing effects among the white population as is any other drug. Of course, on the whole, the amount of cocaine consumed during a year does not compare in magnitude with that of opium, but then opium is prescribed as a medicine and taken by certain classes of the population—notably by the Chinese—far more extensively than cocaine. At any rate, if opium in its different forms stands first in this country in its use as a narcotic, it will be generally allowed that cocaine makes a good second.

In the MEDICAL RECORD of September 7, 1901, the growth of the drug habit, was dealt with editorially, and some statements on the subject made by Dr. A. P. Grinnell in the *Medico-Legal Journal* were referred to. That writer showed that in 130 of the regular pharmacies and in 160 of the general stores in the State of Vermont there were sold to regular customers every month 3,300,000 doses of opium, besides what were dispensed in patent medicines, and what the

physicians prescribed, giving one and a half doses of opium to every man and woman in the commonwealth every day in the year! The inquiry was restricted to the commoner narcotics—opium, morphine, Dover's powder, paregoric, laudanum, cocaine, chloral, and cannabis indica. The amounts given in these instances were so large that Dr. Grinnell was at first led to believe that the vendors estimated by the year instead of by the month. From a consideration of the above, one might be led to believe that drug-taking is manifestly enormously on the increase in this country, but it will be wiser to regard the question from a conservative standpoint, and to surmise that the habit has a much wider scope than formerly, but not to the extent stated in many of the sensational reports which are being issued constantly nowadays. It must be also borne in mind that Vermont was a prohibition State, and therefore should not be taken as typical of the United States as a whole so far as the drug habit is concerned.

According to a writer in a recent issue of the *London Daily News*, Great Britain numbers her victims to the drug habit by the thousands, and in an interview with Dr. Forbes Winslow, the same writer gives the views of that authority at some length. In the course of his remarks Dr. Winslow said: "In my opinion one of the chief causes of degeneration in the human race is indulgence in opium or the drug habit. In China there are upward of three millions of opium eaters, and the number is gradually increasing. In one year the value of opium which was sent into England was over £400,000 ($2,000,000)." Again he asserted that the drug habit is very common in England, chiefly among ladies, and that a large amount of laudanum is consumed by the upper classes in conjunction with alcohol.

It may be taken as proved that the drug habit has increased in both Great Britain and in this country, as it has doubtless increased in most of, if not in all, the civilized countries of the world.

To dwell upon or to emphasize the evil effects of drug-taking is unneccessary, so much has been written and said on the subject that everyone who can read must be well aware that the habit if persisted in destroys a person body and soul.

It goes without saying that the causes for this craving for stimulants and narcotics by the people of the present day are various. One of the principal reasons is the wear and tear of modern life, acting upon a race ever becoming more nervous and active, through living under artificial conditions. The physician is to some extent responsible for the spread and prevalence of the habit, by his frequent lack of discretion in prescribing drugs of a narcotizing nature.

It is well-nigh impossible to put forward an effectual or even partial remedy for this state of affairs. Legislation designed to restrict the sale of narcotics and to render them much more difficult to obtain than is the case at present, might have a restraining effect, but the only true panacea is that the community at large should be brought to a right appreciation of the menace the drug habit is to the health, moral and physical, of the nation. In this missionary work the physician is peculiarly fitted, both by example and precept, to take a leading part.

## ORGANOTHERAPY IN ADDISON'S DISEASE.

Dr. Edward M. Adams contributes to the *London Practitioner* for October a critical review of the effects, in the reported cases of Addison's disease, of the use in some form of suprarenal substance. Prior to the appearance of organotherapy, cases of permanent improvement, or even of apparently permanent recovery, were extremely rare. Now, however, more or less permanent recovery under "specific" treatment is, comparatively speaking, not infrequently seen. As regards the correctness of the diagnoses in the recorded cases, most of which lack post-mortem confirmation, while mistakes may at times have occurred, still there is no sufficient justification for assuming a resolutely skeptical attitude toward the cases as a whole. Moreover, in two cases in which the beneficial effect of organotherapy was least open to objection, the diagnosis has been confirmed by autopsy. And further, a number of cases showed fluctuations corresponding to administration or withholding of the suprarenal substance, relapsing when it was stopped and again improving on the resumption of its administration. The author concludes that there would appear to be a certain class of cases of this infection which derive indubitable benefit from the administration of some form of suprarenal substance, but in any given case it is, so far, impossible to determine in advance its probable response to this form of treatment. In any given case, selected haphazard, the probability obtains that disappointment will follow the trial of organotherapy, but this probability is distinctly less than that against any form of alterative treatment yet proposed. The last word remains to be said upon both the preparation and the mode of administration of the suprarenal substance. The problem seems to be to get a sufficient and continuous dose of the pure and active principle unchanged into the blood stream. Intravenous injection is impracticable.

## A Form of Hog Cholera Not Caused by the Hog-cholera Bacillus.

The Biochemic Division of the Bureau of Animal Industry, under E. A. de Schweinitz and M. Dorset, has been recently carrying on investigations concerning hog cholera, and has discovered that certain outbreaks of the disease were apparently not produced by the hog-cholera or the swine-plague bacilli. This discovery has led the division to institute experiments to determine, if possible, whether or not there are other infectious diseases among hogs in this country than those caused by the hog-cholera and swine-plague bacilli, and also to ascertain what was the etiological agent in those outbreaks of disease which apparently did not depend upon these bacilli for their existence. The experiments have not yet been completed, but sufficient information has been gathered from them to justify the publication of a preliminary note. As a matter of fact, the experiments have reached such a stage that the investigators feel they are in a position to state that there is an infectious disease among hogs in this country which cannot be distinguished clinically from hog cholera, and which may be reproduced by infecting with material which contains no hog-cholera bacilli.

As to the cause of the disease, nothing at the present time can be definitely stated, although it has been demonstrated that the primary cause is

neither the hog-cholera bacillus nor the swine-plague bacillus. The malady is highly contagious, healthy pigs that were allowed to come in contact with sick animals almost invariably contracting the disease within the usual period of incubation. Other animals than hogs do not appear to be susceptible to infection by the disease.

The period of incubation after exposure to sick animals, or after a subcutaneous inoculation of infectious material from sick animals, varies from five to twelve days, the usual time elapsing between exposure and visible signs of illness being seven days. Death generally takes place within seven days after the appearance of the initial symptoms and approximately two weeks after the first exposure to infection.

The post-mortem appearances of this particular type of hemorrhagic hog cholera resemble somewhat closely those of the ordinary acute hog cholera supposed to be caused by the hog-cholera bacillus. This circumstance, combined with the fact that by the methods of inoculation used, without the presence of the hog-cholera bacillus, a case of chronic hog cholera was never produced, led the investigators to suspect that possibly in all outbreaks of acute hog cholera there is some other agent besides the hog-cholera bacillus at work, and that in those cases of acute disease in which the hog-cholera bacillus is found we have to do, not with a pure infection, but with a mixed infection by hog-cholera bacilli and the organisms which are responsible for the disease just described.

When the experiments are completed the Biochemic Division of the Bureau of Animal Industry hope to decide the point as to whether a new hog disease has been discovered. If such shall prove to be the case, it must of necessity have an important bearing upon the prevention and treatment of hog cholera. The experiments so far have shown that the same measures which have been found to be effective in the ordinary forms of the disease, are of equal value in this particular form of hog cholera.

## Southwest Africa as a Health Resort.

Professor Dove writes in highly eulogistic terms of the table-lands of Southwest Africa for those suffering from respiratory diseases. In the *Deutsche Monatsschrift* he describes this region, showing that its health-giving properties are due to its physical conformation. The large quantity of rain which falls in the land south of the equator gives rise to a far more equable climate than that which prevails in the northern hemisphere. The mean temperature is greatly less in the summer in these southern lands, and higher in winter, than in those of southern latitude. Another immense advantage that South Africa possesses over countries of the same latitude consists in the fact that it is composed of a series of plateaus, arranged in terraces one above the other, and rising to a considerable altitude above sea level, with no intervening plains. This elevation renders the air rare and compels persons to breathe more deeply and freely than in regions situated at a lower altitude. The rapid inspiration and expiration of pure air promotes expansion of the lungs and consequent enlargement of the chest, a condition always noticed in those who have made their home in the interior of South Africa. The humidity is slight, the nights are cool, and cold to a degree in winter, but the air is so pure and clear that it is far more healthy to breathe than the cold moisture-charged air of Europe and of many parts of the American continent. Last but not least in the enumeration of the salubrious properties of the South-African climate, is the almost constant flood of sunlight which warms the atmosphere and ground and kills the disease-bearing germs. Outdoor life, owing to the above-mentioned conditions, is almost always possible, with little or no protection. South Africa is the ideal country for consumptives, and may in time to come be looked upon as the natural refuge for the victims of respiratory affections.

## Hospitals for Tuberculous Children.

In no country are children better cared for than in France—in fact, French children are—so far as their physical needs are concerned—the objects of greater solicitude than in any other land. This being so, it is only in the nature of things, that institutions for tuberculous children should be both numerous and well-managed. Mr. John Seely Ward, Jr., has recently returned from a visit to England and France, in the course of which he investigated the manner of treatment of tuberculous children in those countries. He found that in France there are hospitals solely for tuberculous children containing 4,443 beds. The city of Paris supports two such hospitals, both of which are situated at the seaside. There is besides a charitable organization, "L'Œuvre des Enfants Tuberculeux," which supports in the neighborhood of Paris three free hospitals for children suffering from consumption. The building at Ormeson is for those in the incipient stage, at from three to ten years of age, and has 128 beds. At Villier-Sur-Marne consumptive boys are received from ten to seventeen years of age, and there is accommodation for over two hundred. There is also a hospital for tuberculous girls at Noisy.

Mr. Ward, who is a member of the New York Association for Improving the Condition of the Poor, has since his return to this country pointed out that the United States possesses no hospital set apart exclusively for children suffering from tuberculous diseases, and has stated that the association he represents may erect one. This would be a most commendable undertaking, and for the good of not only the sufferers themselves, but of all those who live in their vicinity.

## Dysentery and Its Relation to Enteric Fever.

The report of the British Commission appointed to inquire into this subject in relation to the mortality from enteric fever during the South-African war has recently been published, a summary of which was given in the *British Medical Journal*, September 12. The commissioners were: Lieutenant-Colonel Bruce, Col. Lane Notter, and Prof. W. J. Simpson.

Colonel Bruce who conducted the bacteriological investigations came to the following conclusions: (1) That dysentery in South Africa is not caused by amœbæ, as there is some reason to believe is the case with the dysentery of other countries. (2) That the organs in dysentery are absolutely sterile. Hence unlike enteric fever, the causal agent confines itself to the intestines. (3) That in the large intestine no particular species of microorganism stands out prominently as in the case of cholera. (4) That there is not sufficient evidence in this work to advance the theory that some of the normal inhabitants of the intestines belonging to the coli group take on a pathogenic power. (5) That there is no connection between dysentery and enteric fever, Eberth's bacillus not being found in the organs or intestines of dysentery. (6) That there is a certain amount of evidence to show that so-called cases of dysentery, following enteric

fever are relapses of enteric, in which the disease has attacked the large intestine.

Professor Simpson's report is instructive in a high degree, dealing as it does thoroughly and exhaustively with the subject of enteric fever in its relation to those engaged in the South-African campaign on the British side. He gives the following summary of the conditions which caused the insanitary state of large camps: (1) Surface supplies of water and their liability to pollution by dead animals, or excrementitious matter, or surface drainage, or all combined. (2) The imperfect and ill-considered disposal of carcasses of horses and oxen. (3) Defective covering of latrines, proximity of litter, manure and refuse heaps; and fouling of the ground with urine and slop water, causing risk of infection of food from flies and from possible contamination of boots, clothes, utensils, and hands. (4) The absence of organized establishments for the cleansing of camps that have been occupied, the absence, also, of arrangements for the distribution and location of regiments on clean ground, and the consequent occupation of the same camps successively by different regiments.

The conclusions arrived at by Professor Simpson closely agree with those of the commission appointed by the Government of the United States to investigate into the condition of the camps during the Spanish-American war. Further force is added to the argument that it is absolutely necessary to keep such camps as clean as possible, and to use every precautionary measure, if disease, and especially typhoid fever, is to be kept away.

---

### Etiology of Sleeping Sickness.

During the past two or three years much has been heard of this somewhat mysterious disease, which affects the negroes of a portion of Africa, principally the West Coast. In the Medical Record of April 25, 1903, the report that Dr. Aldo Castellani, a member of the commission sent out by the British Royal Society to Uganda, had discovered an organism which he thought to be the cause of sleeping sickness, was referred to editorially. The same subject was commented upon in an editorial on June 27, 1903, when the findings of the Portuguese Commission with regard to the cause of sleeping sickness were dealt with. The New York *Sun*, November 7, published a despatch from London stating that the cause of sleeping had been definitely discovered. The investigations—according to the despatch—were carried on by the British Governmental Commission. Buvuma Island, Uganda, was the seat of the investigations. This island has been practically decimated by the disease. The first step in the discovery was the observation of trypanosomes in the cerebrospinal fluid in all cases met with. The credit of this discovery is generally accorded to Castellani.

Christy read a paper in the Section on Tropical Medicine at the recent meeting of the British Medical Association, in which he gave the results of investigations made by him in the island of Buvuma. He travelled all over the island and found that almost all the huts contained a case or two of sleeping sickness. He likewise found that practically all the cases occurred near to the water's edge, on the lowest lying parts of the island, and that the huts were invariably surrounded by vegetable or forest growth. On the other hand, the high ground was exempt from the disease. The same characteristics were observed in all the sleeping-sickness area. Such localities are exactly those which the tsetse fly (genus Glossina) infest, low-lying situations near to water and amongst trees or scrub. Colonel Bruce, who has been studying the subject of trypanosomiasis and sleeping sickness in Uganda, found Glossina palpalis to be fairly common in certain parts along the lake shore. Christy, therefore, drew the obvious inference that there must be a relationship between sleeping sickness and the tsetse fly (Glossina palpalis).

The despatch to the *Sun* would seem to show that Christy was right and that the tsetse fly (Glossina palpalis) is, indeed, the cause of sleeping sickness.

---

## News of the Week.

**The Life History of the Organism of Smallpox.**—Dr. Gary N. Calkins delivered a lecture on this subject at a meeting of the Biological Section of the New York Academy of Sciences, on November 9, 1903. He said that Dr. Councilman had pointed out that the organisms found in vaccina were limited to the cell bodies of the Malpighian layer of the skin, whereas in smallpox they were found both in the cell bodies and the cell nuclei. He also showed that the inclusions were protozoa. The lecturer said that in the parasitic diseases due to the protozoa there was usually some phase of the disease which corresponded with some phase in the sexual development of the parasite. The ordinary asexual development of the organisms took place in the cell bodies of the Malpighian layer of the skin, while the more important sexual reproductive processes occurred in the nuclei of those cells. He had been fortunate enough to be selected by Dr. Councilman to work out the life history of the organism of smallpox, and through the courtesy and liberality of the same gentleman he was permitted to present those results at this time. Most of the work had been done in connection with the epidemic of smallpox in Boston. His own work had been done mainly upon twenty-two cases, representing nearly every variety of smallpox. It was below the pustule that one found the organism of smallpox. This organism was a minute, homogeneous body situated in the cell protoplasm.

The lecturer then described in detail the various phases of the life history of this organism, the *Cytoryctes variolæ* Guar., by the aid of a series of lantern slides, many of them photographs from actual specimens. He pointed out that in vaccina only gemmules formed, the remainder of the process of development being, for some reason, inhibited. In the late vesicle stage of true smallpox there was found a most characteristic process of reproduction, an autoinfection, *i.e.* the formation of the pan-sporoblast. Dr. Calkins said that, as long ago as 1896, while making some cultures from the protozoa of another class, he had noticed that the nucleus of these forms was invested in many cases by a peculiar body, at the time unknown to him. The specimen was labeled "A Parasite in the Nucleus," and was not thought of again until he became acquainted with Dr. Councilman's specimens last spring. The specimen was then looked up and found to be apparently identical with the smallpox germ. Although there was about one chance in several million that this specimen represented the exogenous phase of the smallpox organism, it was thought proper to study it thoroughly and remove every doubt on this point. Personally, however, he believed it was a similar parasite, but was not identical with the smallpox organism. The speaker, in closing, compared the cycle of malaria,

a disease due to a protozoon, with the cycle of smallpox.

Dr. Brinckerhoff, in discussing this paper, said that he had inoculated twelve apes with this organism, and in each case there had been a development of a lesion analogous to the vaccina lesion; indeed, the disease in the monkey was found to be comparable in its clinical course, in the evolution of the lesions, and in the general constitutional reaction with variola inoculata in man. In every case in which a secondary exanthem developed, the lesion was found in that. It had been possible by this mode of experimentation to determine quite accurately the time relation between the various stages of the parasite and the evolution of the lesion, and these findings were perfectly in accord with the results obtained by Dr. Calkins on the human lesion. The monkey was subject to both vaccina and variola, and hence this animal was particularly well suited for the final demonstration of the minute details of the complete life history of the organism of variola.

**The German Emperor's Throat Trouble.**—Dr. Moritz Schmidt, on Saturday of last week, removed a tumor from the larynx of Emperor William. The operation was successful, and the tumor was found, on examination by Dr. Johann Orth, to be a mucous polypus of the left vocal cord. The growth was pronounced benign.

**William Pierson Medical Library Association of Orange, N. J.**—At the annual meeting of this association on November 5 the following Board of officers were elected: *President*, Dr. Thomas W. Harvey; *First Vice-President*, Dr. R. C. Newton; *Second Vice-President*, Dr. R. D. Freeman; *Secretary*, Dr. J. H. Bradshaw; *Librarian*, Dr. Henry Pulsford; *Executive Committee*, Drs. T. Y. Sutphen W. B. Graves, and Mefford Runyon.

**American Electro-Medical Society.**—The first annual meeting of this society will be held December 1, 2, and 3 at the Masonic Temple, Chicago. This society, which already numbers over one hundred and fifty members, has for its object "investigation in electricity and allied sciences and the encouragement of their application to medicine and surgery by the formation of district and local societies." The preliminary program contains the names of thirty men who will read papers. The secretary of the society is Dr. T. Proctor Hall of Chicago.

**Examinations for Superintendent and Resident Physician in the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis.**—The State Civil Service Commission will hold open competitive examinations for the above mentioned positions, November 28, 1903, in various cities throughout the State. Intending competitors must fill out application blanks and file them in the office of the Commission before noon of November 23. Applicants will be duly notified of the time and place of examination. Non-residents of the State will be admitted. The requirements and conditions of examination are as follows: *Medical Superintendent.* Probable salary $3,500 a year with quarters and maintenance for the superintendent and his family. The duties of the position are defined by chapter 416 of the Laws of 1900, which further provides that such medical superintendent shall be a well-educated physician, a graduate of a legally chartered medical college, who has had at least six years actual experience in the practice of medicine, including at least one year's experience in a general hospital. Subjects of examination and relative weights: Experience, education and personal qualifications, 4; written examination covering general medicine; hospital administration; pathology, bacteriology and therapeutics of pulmonary tuberculosis, including dietetics and sanatorium treatment, 3; practical examinations of patients for diseases of the chest, 3. The written examination will be held in any of the cities named on the application on November 28. The practical test will be held at a later date and place (probably Albany), of which candidates successful in the experience and written examinations will be duly notified. *Resident Physician.* Probable salary from $900 to $1,500 a year with quarters and maintenance. Duties to be prescribed by the medical superintendent under the direction of the Board of Trustees. Candidates must be regularly graduated physicians and have had at least two year's experience in the practice of medicine, including one year's actual experience in a general hospital. Subjects of examination and relative weights: Written examination covering anatomy, physiology, materia medica and therapeutics, chemistry, theory and practice, surgery; also a special examination in pathology of pulmonary tuberculosis, in bacteriology and descriptive laboratory methods, 6; practical examination in the physical diagnosis of diseases of the chest, in the examination of sputa, blood, urine, and other pathological material, 4. The written examination will be held in any of the cities named on the application on November 28. The practical test will be held at a later date and place (probably Albany), of which candidates successful in the written examination will be duly notified. Further particulars and application blank may be obtained by addressing: Chief Examiner, State Civil Service Commission, Albany, N. Y.

**College of Physicians of Philadelphia.**—At a stated meeting, held November 4, Dr. Ward Brinton exhibited and read "A Contemporary Manuscript Criticising the Treatment Pursued in the Last Illness of General Washington." Dr. Wm. J. Taylor reported a case of tumor of the brain with operation. The patient was a boy, fifteen years old, previously healthy and with a good family history, who had been struck upon the head as a result of punishment on the part of a strenuous teacher. In the course of a short while a swelling appeared in the right temporal region, together with headache, vomiting, optic neuritis, and ocular palsy. Operation was undertaken, and a tumor-mass of moderate size removed. The growth, clinically, suspected to be an osteosarcoma, was found to arise from the dura, and microscopical examination disclosed the fact that it was an endothelioma. The patient was much improved for a time after the operation, but the growth recurred and remained uninfluenced by the *x*-rays. Another surgeon, into whose hands the boy fell subsequently, ligated the carotid artery in the hope of starving the new formation, but death ensued. Dr. John M. Swan read a paper entitled "Mercurial Nephritis," reporting the case of a woman who presented a scaly cutaneous eruption, together with a family history of psoriasis. The lesion of the skin being considered syphilitic, the patient was for some time treated actively with mercurials. Symptoms of nephritis that appeared were also looked upon as syphilitic. Other symptoms of mercurialism developing, the urine was examined and the presence of mercury demonstrated. Notwithstanding the withdrawal of the metal for therapeutic purposes, the presence in the urine was demonstrable for more than a year after the last dose had been administered, in conjunction with albumin and tube-casts. Dr. Francis T. Stewart reported a case of volvulus

of the omentum, a rare condition, of which eight other cases were found recorded in the literature. In none was the diagnosis made accurately. In some hernia was suspected, in others appendicitis, in still others ovarian disease.

**Reformation of Hot Springs.**—The Interior Department at Washington has taken energetic action to abolish the nuisance and scandal of medical drummers at Hot Springs, Ark. It has prescribed a number of rules for the guidance of bath-house proprietors and physicians, one of which prescribes that "No bath house supplied with water from the Hot Springs Reservation shall permit any person to bathe therein who is under medical treatment, unless the applicant for baths presents satisfactory evidence that he, or she, is the patient of a physician duly registered at the office of the Superintendent of the Hot Springs Reservation as one qualified to prescribe the hot waters from the Hot Springs, and who is known not to engage in drumming for custom." Another rule reads: "Physicians desiring to prescribe the hot waters of the Hot Springs, either internally or through the medium of the baths, must first be registered at the office of the Superintendent of the Reservation. Registration will be accorded only to such physicians as are found, by the board of physicians designated by the Secretary of the Interior, to have proper professional qualifications and character, and who do not engage in drumming for custom. The solicitation of patronage, through the medium of drummers, by registered physicians is prohibited; failure to observe this requirement will be sufficient cause for cancellation or revocation of registration." The *Hot Springs Medical Journal* states that the Federal Board received the credentials of the physicians in the place some time ago, and sent a report of the results of the inspection of them to the Interior Department. This will undoubtedly result in the redemption of Hot Springs from the horde of advertising quacks who have for so long brought discredit on the place.

**Mikulicz on American Surgery.**—Prof. Johan von Mikulicz-Radecki, lecturing at Breslau on Friday of last week on his recent trip to the United States, said he found more fruitful ideas among the American surgeons than among the French and English. He added: "The time is past when we were the givers and the Americans the receivers. The American character has as a fundamental feature unlimited self-confidence, and the American believes he can do anything he wishes."

**St. Francis Hospital**—At a meeting of the Medical Board of St. Francis Hospital, held on November 3, 1903, a resolution was adopted to the effect that each consulting physician and surgeon regularly connected with St. Francis Hospital shall be privileged to care personally for such private patients as he may desire to place in the hospital for operation or treatment. The number of patients under the charge of any individual member of the consulting staff shall, however, be limited to two at any one time.

**The New Health Commissioner**—It is announced that Drs. W. T. Jenkins, John H. Girdner, and John H. Cosby, are candidates for the office of health commissioner of New York City under the new administration.

**A Striking Antitoxin Demonstration.**—Some days ago diphtheria broke out among the inmates of the New York State Reformatory at Elmira, and within a week there were fifty cases and three deaths, among those attacked being the assistant resident physician and others of the official staff. On November 10 Dr. Robertson, the superintendent, obtained a large supply of antitoxin from the laboratory of the State Department of Health. Every inmate of the institution was inoculated, and on the following day Dr. Robertson reported that the epidemic had been completely checked.

**American Röntgen Ray Society.**—The fourth annual meeting of this society will be held at the University of Pennsylvania, Philadelphia, on December 9 and 10, 1903, under the presidency of Arthur W. Goodspeed, Ph.D., of Philadelphia. The sessions will be held in the audience room of Houston Hall of the Houston Club of the University of Pennsylvania. The exhibition of apparatus will be down stairs, in the reading-room of the Houston Club. Under the chairmanship of Dr. P. M. Hickey of Detroit, Mich., an exhibition of prints is being arranged for. A lantern with competent operator will be on hand and ready for use at any time. Those who desire to illustrate remarks need only to bring along the slides. The Normandie Hotel, Thirty-sixth and Chestnut streets, has been designated as official headquarters. The preliminary program contains the titles of eighteen papers. The secretary of the society is Dr James W. Bullit, 205 West Broadway, Louisville, Ky.

**Closure of a Japanese Medical School.**—The proprietors of the Saisei Gakusha, a medical school in Tokio, which has existed for twenty-seven years, recently closed the school and also the hospital attached to it. They were obliged to take this step the *Sei-I-Kwai Medical Journal* states, owing to the Education Department's refusal to give permission to the school to call itself a college. Recently the law schools in Tokio transformed themselves into colleges in order to impress the public mind, and the medical school wished to take a similar step, but being met with refusal of the Government the proprietors thought that the school could no longer hold its position against its rivals, and hence their action. Incidentally some 3,000 students, 600 of whom have been in regular attendance, find their future prospects seriously affected. The hospital attached to the school contains about 150 charity patients.

**Committee on Program of the State Society.**—The President of the Medical Society of the State of New York has appointed the following business committee on program for the next annual meeting to be held January 26, 27, and 28, 1904: Drs. H. A. Fairbairn and G. R. Butler of Brooklyn, and Andrew MacFarlane of Albany.

**Protest against a Sanatorium at Capri.**—The population of the Island of Capri is indignantly protesting against the plan of Professor von Behring to transform the villa which he bought from the family of the late Herr Krupp, the famous gunmaker of Essen, into a laboratory for the manufacture of antitoxins and a sanatorium for the treatment of people affected with tuberculosis. The people of Capri say that it would injure the reputation of the island, which depends for its revenues almost entirely on foreign visitors. They have interested several members of the Chamber of Deputies in their protest and hope to be able to prevent the carrying out of Behring's project.

**Gifts to Hospitals.**—Mr. Daniel G. Reid of this city has given $50,000 to the trustees of St. Stephen's Hospital at Richmond, Ind., for the erection and equipment of a new hospital building. Mrs. Margaret J. Plant has announced her intention to build and present to St. Luke's Hospital in this city an additional pavilion, thus pursuing the line of development laid down in the plans for the erection of ten pavilions, five of which have already been built. The new building will be for the care and treatment

of private patients, and will be located on the southeast corner of the block overlooking Morningside Park.

**The Plague in Rio de Janeiro.**—The United States Consul at Rio de Janeiro telegraphed the State Department a few days ago that the bubonic plague, which has been prevalent at Rio for several months, had increased, and that disinfection is now obligatory for vessels leaving there for other Brazil ports.

**A New Antiserum for Cancer.**—Dr. Otto Schmidt of Cologne claims to have isolated the parasite of cancer, and says that all the alleged parasites of varied appearance described by Gaylord and others are only varieties of the same microorganism. He says he has obtained an effective antiserum, and has also been able to diagnose malignant disease by means of a Widal reaction. The serum does not remove the growth, but takes from it its character of malignancy, and thus makes it possible for the surgeon to extirpate it without fear of recurrence. The discoveries of Schmidt were recently described by Dr. Jesse Johnson in a paper read before the Abernethian Society of London, but were received with considerable scepticism by the members of the society.

**Yellow Fever** still prevails at Laredo, Tex. On November 8 there were 12 new cases, but no deaths were reported. The total number of cases up to a week ago was 723, with 66 deaths. In Monterey, Mex., there is no abatement in the epidemic and it is believed that there have been nearly 20,000 cases of the disease there during the past year. The mortality is about 5 per cent. All the towns on the Mexican Central Railroad between Saltillo and Laredo are believed to have suffered from the disease.

**Obituary Notes.**—Dr. EMIL ROSENBERG of this city died on November 4 at the age of seventy-four years. He was born in Germany and was graduated in medicine from the University of Berlin in 1855. He came to this country in 1868. He was closely identified with insurance work, having been medical director of the Northwestern Mutual Life Insurance Company for many years.

WILLIAM B. O'ROURKE, superintendent of the Metropolitan Hospital, Blackwell's Island, died there on November 5 from cancer of the stomach. He was fifty-five years old and was born in this city. In February, 1890, Mr. O'Rourke was appointed steward of the Homœopathic Hospital on Ward's Island. He became warden of Bellevue Hospital in May, 1891, where he remained until 1896. He was in 1898 again appointed Warden of Bellevue Hospital, and from there was transferred to the Metropolitan Hospital.

Dr. WILLIAM W. SEELEY of Cincinnati died on November 7. He was a graduate of the Medical College of Ohio in the class of 1864. He was a well-known oculist, and held the chair of ophthalmology in the Medical College of Ohio for many years.

Dr. FRANKLIN V. VANARTSDALEN died in Philadelphia on November 5 at the age of seventy years. He was graduated from Jefferson Medical College in the class of 1856. He retired from the active practice of medicine a number of years ago.

Dr. EDGAR C. LAKE of Amsterdam, N. Y., was burned to death on November 10. He was forty-three years old, and was a graduate of the College of Physicians and Surgeons in this city.

Dr. I. K. RAINEY died at his home in St. Augustine, Fla., on November 9. He was born in Illinois, and was graduated from the St. Louis Medical College in 1859. He was a surgeon in the federal army during the civil war, and was in Gen. Fitzhugh Lee's corps during the war with Spain. He was department commander of the Grand Army of the Republic.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

THE HARVEIAN ORATION—THE HUXLEY MEMORIAL LECTURE—SIR W. S. CHURCH ON THE STATE OF THE PROFESSION—DINNER OF THE ROYAL ARMY MEDICAL CORPS TO MR. BRODRICK—GUILD OF ST. LUKE—THE LATE MISS HICKMAN.

LONDON, October 23, 1903.

THE two hundred and forty-seventh Harveian anniversary was celebrated in the usual way on Monday afternoon at the Royal College of Physicians. Dr. W. H. Allchin was the Harveian orator. The President, Sir William Church, wearing his black and gold robes of office, presided with the Carolinian mace reposing on a velvet cushion before him. A fair number of the fellows and members, some in academical robes, were present. These Harveian orations have so often repeated the tale of the discovery of the circulation and defended Harvey's claim to honor that nothing new can be expected. The orator, therefore, did not attempt this, but passed to the other part of his duty, that of commemorating benefactors of the college—not forgetting Harvey himself, who left his estate to it, and said they should remember those whose investigations had enhanced its reputation and imitate their example. Dr. Allchin then recalled the fact that Harvey was an anatomist, and that his knowledge and practice of anatomy enabled him to carry out his experiments and appreciate their results. Following up this point he considered the influence of anatomy on the progress of biology. Tracing the successive phases of structure from the most obvious to those revealed by the microscope and by chemical and electrical researches he remarked that in various departments of physiology there is yet much to be done to determine the ultimate structure of the tissues concerned. The phenomena observed in muscle, nerve-fiber, and gland cell offer problems for solution, and show that to the term structure we must give a wider range of meaning in order to reach into regions where theory has to take the place of fact. However true it may be that for a general conception of the physics of the circulation Harvey was beholden to his knowledge of anatomy, it is just as true that for our later acquired information of the share taken in the movement of the blood by the arteries an acquaintance with the structure of these vessels is necessary in order to refer their tone and elasticity to their respective tissues.

The problem that Harvey solved was broadly a mechanical one, but does not end with such information as anatomy and histology supply. For the complete understanding of the electrical and chemical changes which are associated with the passage of the nervous stimulus, and the muscular response we require to know what are the underlying molecular rearrangements and alterations in chemical constitution crudely represented by the formation of certain waste products. But just here precise knowledge fails and we turn to theory. When the limits of visibility with the most perfect instruments is reached the separate investigation of structure and function is no longer possible. The molecular constitution of living matter becomes conceivable only in terms of action. No deeper secrets of nature exist to be searched out by observation and experiment—none would more benefit man in their discovery. To that investigation, therefore, in obedience to the precept of Harvey, Dr. Allchin exhorted his audience to turn.

At the conclusion of the Harveian oration the president presented the following medals:

The Weber-Parkes medal and prize for investigations in the treatment of tuberculosis to Dr. Hugh Walsham and Dr. Walter J. Horne; the Moxon medal for clinical medicine to Dr. Hughlings Jackson; the Baly medal for physiology to Dr. Newport Langley.

Prof. Karl Pearson delivered the Huxley memorial lecture on the 16th instant. He took for his subject the "Inheritance in Man of Moral and Mental Characters and Its Relation to the Inheritance of Physical Characters." He has spent much time in collecting statistics with a view of elucidating the condition of the nature in these respects. He dealt with his figures as a master, and some of his audience must have followed him only by the closest attention and determined effort. I can therefore only mention points in his conclusion: General health he held to be inherited just as stature and head measurements. The same law governed mental and moral characters, consequently good qualities were in the breed and not created by the environment, though they might be cultivated by it. But the parental stock was of the first importance, education and other influences were quite secondary, or at least what could be gained thereby depended very much on the stock. I don't know

that this conclusion differs very much from the popular notions of the value of good breeding or from the experience of schoolmasters. You cannot develop a genius out of a dull boy or girl by the most prolonged education. The children of the physically feeble are heavily handicapped in the struggle of life, and it may well be that mental and even moral qualities are apt to fade in the contest. But even so we cannot altogether exclude environment.

We have heard much of our national decadence in physical qualities, though the pessimists have not convinced the nation that it is only a dying one. Professor Pearson seems to think that we are declining in the other qualities, and he blames the intellectual classes, which, he says, for the last forty years, enervated by pleasure and leading a wrong life, do not furnish the right stock to carry on the work of the empire. The remedy would be restraining the breeding by bad stock and increasing the fertility of the good. This, of course, can be done in the breeding of animals, but how can a nation accomplish it? Education is the modern panacea for everything, but if we tell men they ought not to marry, how many will heed us? Even if we admit that physical and psychical qualities march in parallel lines it is hopeless to expect to persuade the feeble or degenerate that their duty is to die out and leave the world to a better breed. And as to this better breed there are many who will deny its existence and say such views, though interesting to speculate about, are improved and, even if true, outside of practical consideration.

Sir W. S. Church gave an address on the 13th at the West London Hospital, in which he expressed satisfaction with the present state of the profession in many respects. He declared it to be impossible to attain the highest degree of skill and knowledge in all departments, and then by a curious *non sequitur* passed on to a mild protest against specialism. He was "filled with admiration" of the general practitioners who are, as a rule, "well up in their work" but would be the "first to repudiate the title of specialists." Then admitting that some specialists are "honest and honorable" he went on to enumerate some of the fashions in physic which have passed by, such as tracing all the ills to which flesh is heir to acidity or gout, or in females to versions, malpositions, etc., or in children to adenoids or phimosis, and at another time proposing abdominal exploration for all internal complaints. Really the president of the Royal College of Physicians seems a little confused in his reminiscences. He should look up the persons who indulged in these fashions and mark how many were honored fellows of his own college.

Would the president put down these persons? Would he even put down quacks who have no diplomas at all, no medical knowledge? No, occupying a high place in the profession, he is content to see them prey on the public to the injury of the general practitioner he professes to admire. Why? Because it appears to him that it would be an unwarrantable interference with personal liberty for the State to say you shall not receive advice as to your health from whom you please. It would be a monopoly—to him apparently a terrible bogey. He must know that the sister profession of the law is a close monopoly. Anyone pretending to act as a lawyer gets short shrift from the court. The rights of property must be protected. Surely a man's health is more important than his pocket. No one proposes to prevent a man asking advice from whom he likes.

The person to penalize is not the victim—the patient—but the fraudulent pretender, who takes the sick person's money under false pretenses. Sir William Church dwelt on the complete ignorance of the public which renders them so credulous, and said mankind was ever alike, and his credulity does not grow less with advancing times, and we have only to look at the advertisement pages of the newspapers to see this. Alas! that this is too true. But does it not show that the ignorant victims should be protected. We punish men in other cases for obtaining money under false pretenses, why not here? And why not prosecute the newspapers as "accessories before the fact" to the fraud carried out by their aid.

Mr. Brodrick responded to the toast "our guests" at a special dinner given by the Royal Army Medical Corps on Wednesday. He said when he joined the war office in 1886 there was one universal cry in Parliament and in the Press for a great reduction in the Army Medical Department. Accordingly reductions were made which they had ground to deplore. But the British public and the House of Commons never seem ready to take the responsibility they force on those who represented them. He had been accused of putting things too much into the hands of military men. The more the army could be conducted by those naturally in authority over it, the better, but they needed a strong permanent civilian support, because it was a Parliamentary army and the House of Commons was supreme. After referring to the steps which were being taken to bring the military hospitals up to date Mr. Brodrick expressed the hope that in the near future there would come into existence a medical reserve versed in military requirements which would be fit to supplement in war time the officers serving in the Army Medical Corps.

Upward of two hundred doctors, many in academicals, assembled on Wednesday evening at St. Paul's Cathedral to hear the choral service and sermon arranged by the Guild of St. Luke. This service has now become an annual function. The preacher was Prebendary Villiers, who took as text Job xxxii, 8. He remarked that the clergymen and the doctor were constantly in contact with the problems of suffering. It might be that suffering was a punishment for sin, but it was never safe to argue that it was. The problem, if it could be read at all, could be only by the incarnation, the lesson of which was trust in God. Without that, all was a burdensome enigma. Unbelief, he declared, was not infrequently of moral origin.

The mystery of the disappearance of Miss Hickman, the lady doctor, who left the Royal Free Hospital on the 15th of August and had not since been heard of, has been to a large extent solved by the discovery on Sunday of her body in an enclosed copse in Richmond Park. The easy position in which the body was lying, on the left side, suggests that she must have lain down to sleep. The copse is a small enclosure, but strictly preserved for small game, and so the body remained undiscovered for this long period. It is greatly decomposed, but the clothing, watch, a medal, and fountain pen have been identified. The discovery was made by some little boys who were trespassing in search of chestnuts, and found the body under a large chestnut tree, partly concealed by low bushes. The inquest was opened on Wednesday. The police surgeon, Dr. Gardiner, Dr. Seward, and Professor Pepper testified that the autopsy was entirely negative as to the cause of death. There was no sign whatever of violence. As it transpired that a bottle was found about nine feet away the inquest was adjourned to November 5.

## OUR PARIS LETTER.

(From Our Special Correspondent.)

WIDAL'S RESEARCHES REGARDING THE INFLUENCE OF VARIOUS DIURETICS ON THE SECRETION OF CHLORIDES—ROUX'S TREATMENT OF APPENDICITIS—SCHOTTELIUS'S EXPERIMENTS ON CHICKENS AND STERILIZED FOOD—ROTHSCHILD'S TREATMENT OF GASTROENTERITIS BY LACTIC ACID IN MILK—CARBONIC ACID AS A MEANS OF DESTROYING RATS—A RADIOGRAPH OF GALLSTONES.

PARIS, October 23, 1903.

Dr. Fernand Widal has been studying the effect of chloride of sodium on the kidneys in acute nephritis, and in his recent investigations he has concerned himself with the comparative effect of various diuretics on the elimination of chlorides. Ordinary salt would seem to be the great cause of œdema in acute nephritis, and its suppression from the food given has been followed by manifest results, which Widal described last June in an article published in the *Presse Médicale*. Two weeks ago Widal and Javal published another article in which they gave the results they had obtained in treating a case of acute nephritis by squill, theobromine, digitalis, and nitrate of potassium. The patient, a man fifty-three years old, had had a pseudomembranous angina fifteen years ago. Last April, nocturnal dyspnœa, and in July œdema. In a first series of experiments no drugs were given, and it was found that by putting the patient on a milk diet there was decrease of the œdema, weight, and albumin. This continued during a second period when food without salt was given him. In a third period it was found sufficient to add 6 to 10 gm. of chloride of sodium to his daily food to see all these symptoms modified, there being an increase in the quantity of albumin excreted, and in the weight and œdema. The patient was left on this diet and various drugs given him. Forty centigrams of powder of scilla were given daily for four days, and were found to have no effect. The albumin remained where it was, and the œdema increased. Theobromine was given for four consecutive days, 2 gm. each day, and the result was immediate. The weight diminished over thirteen pounds, the quantity of urine excreted was much larger, 3,675 c.c. instead of 1,045, the albumin disappeared almost completely, and the elimination of chlorides went from 3 gr. 85 to 18 gr. 68. For three days no drugs were given, and immediately the weight increased, the quantity of urine diminished, the albumin went up to 80 cgs. and the elimination of chlorides diminished noticeably. Nitrate of potassium was next tried, and it was found that the œdema increased, the albumin went up to 2 gr. 10, and the

chlorides were diminished. The patient came back to the hospital last September and digitalin was tried, with poor results, the œdema kept on increasing, and the weight increased 1,600 gms. in four days. It would therefore seem right to conclude that digitalis cannot produce good effects in epithelial nephritis. There is but slight increase in the elimination of the chlorides, whereas in heart disease the contrary is seen, as indicated by Huchard and Merklen.

Dr. Roux of Lausanne has shown himself conservative in the treatment of acute attacks of appendicitis, and Dr. Gaudin, one of his pupils and former assistant at his clinique, has recently published an article on this subject in which the views of his master are given. He chose a certain number of typical cases of appendicitis and divided them into five categories: (1) the usual form; (2) the retrocæcal one, with consequent abscess; (3) the meso-cœliac form, in which the appendix is found in the folds of the small intestine; (4) the pelvic form, with abscess; and lastly, a pernicious form, very seldom seen, in which there is no peritoneal reaction, death taking place almost invariably. With the exception of this last one, all these forms of appendicitis have a natural tendency to limit themselves, if the right medical treatment is carried out, and according to Dr. Roux, 95 per cent. of all cases of appendicitis require no operation, provided the treatment instituted by the physician is what it should be. The following rules should therefore be carried out: Absolute rest, the patient not being moved from his house. No purgatives. No solids nor liquids for forty-eight hours. In case there is any pain laudanum may be administered, or preferably, opium suppositories, and a few drops of liquid may be given at stated intervals, provided the patient has not vomited. The icebag is indicated only when there is distention. No enemas are to be given, a rectal tube being inserted to remove the efflatus. Only neglected cases will, as a rule, need to be operated upon, and the indications of the operation are as follows: discrepancy between the pulse and the temperature, suppression of free enuresis, dry tongue, very frequent pulse and high temperature, the change in the expression of the face showing a severe infection. Local symptoms, such as fluctuation, naturally justify an operation, which is, however, rarely found requisite in Roux's service, since the physicians in the neighborhood of Lausanne have ceased to use purgatives. In a small number of cases, in which the diagnosis of appendicitis had been made previously, it was found advisable to operate in the first twenty-four hours. Gaudin ends his article by remarking that a death in Roux's service from appendicitis is exceedingly rare, though, of course, the operation *à froid* is carried out as a routine measure when the patient has recovered.

Schottelius, a German physician, has carried out some experiments on chickens, which would tend to show that some bacteria are necessary to life. Five new-born chicks were fed on sterilized food, and notwithstanding the fact that they ate more than some other chickens, which were given ordinary food, they lived only from eleven to twenty-nine days.

There was no increase in size, and yet the digestion seemed to take place normally. Schottelius made another experiment, which consisted in giving some of the chickens a culture of bacillus coli gallinarum. There was an instantaneous change, the chickens beginning to grow immediately.

Dr. H. de Rothschild, a member of the well-known family of bankers, has recently communicated to the Academy of Medicine a novel treatment of gastroenteritis. Instead of suppressing completely all food, he centrifuges milk, so as to remove the butter, and then acidifies it by means of pure lactic acid. From 30 to 60 c.c. are given to the children. The results would seem to be quite surprising, the temperature dropping in a short space of time.

French obstetricians are looking with more and more favor on early and energetic treatment of all cases of eclampsia by means of immediate delivery. Dr. Maury has written a thesis on this subject, in which he describes this mode of practice. If labor supervenes during eclampsia, it should be hastened, whatever may be the presumed date of pregnancy. When such is not the case, and yet the attack is severe, induction of labor is the best treatment, quickness and celerity being practised in removing the child. In some cases the condition of the mother is such, that the only means of saving the child is to carry out *accouchement forcé*. After the eighth month has begun this should always be done, if the usual treatment is not rapidly effective.

Experiments have been carried out of late in Marseilles to ascertain if carbonic acid might not be used as a means of destroying rats on board ship. Forty cubic meters were used for a space of 120 meters. The hold was kept closed three hours, and then thoroughly ventilated by means of the same apparatus. A large number of rats which had been purposely placed in the hold were found dead, not one having escaped. There is no odor produced by this technique, and the merchandise cannot be spoiled.

Drs. Mauclaire and Infroit have been able to obtain a radiograph of gallstones. They described their technique at a recent meeting of the Academy of Sciences. A small tube, osmo-regulator, is charged by means of an eight-plate static machine, and held at a distance of 75 cms. from the radioplate, which is placed underneath the patient. The abdomen is flattened down by means of a band of linen. The tube that was used was but slightly penetrating and the pose lasted only ten minutes.

## VOMITING, GREEN STOMACH CONTENTS, APPETITE.

To the Editor of the Medical Record:

Sir: Dr. Benedict in his letter, published October 31 last, does not bring positive proofs in refutation of my statements, but asks questions. Allow me to begin in the same way and ask his own questions, a little modified, over again. Why is it that ordinary gastric contents or a few drops of mucus do not become highly irritant to the mucous membrane of every one who passes from dry land to a boat? How does a hair in the butter on the plate not suddenly transform agreeable food into irritating gastric contents in most persons? The story of the man with the filthy stories is luckily conceded to its probably being a myth. At the very outset Dr. Benedict asserts that the very irritation is a reflex action. I beg to differ and beg to make the statement that until the defenders of "reflex action" bring positive proofs instead of vague assumptions I shall remain a heretic in matters of medical mysticism. I swear by chemistry. Dr. Benedict undoubtedly concedes that there is a multitude of persons who do not get seasick. I am not aware that the positive statement of Dr. Benedict that "ordinary gastric contents" become highly irritant when passing from dry land to a boat is borne out by actually testing the stomach contents of the individuals, and that such stomach contents have actually been found absolutely normal. Why one gets seasick is a question yet to be answered. I confess I cannot answer it at present. But I am sure that the stomach itself comes in for its share. To make a statement that ordinary gastric contents produce vomiting under such conditions without having positive and actual proofs of the stomach contents being "ordinary" is rather risky for one professedly scientific. That persons can empty their stomach contents voluntarily by compressing their stomachs and intestines with the diaphragm and abdominal muscles is a fact which is utilized in our method of "expression" of the stomach contents. And it is my opinion that the illustrations of reflex vomiting given by Dr. Benedict are illustrations of voluntary contractions of the muscles just mentioned. It is not the hair in the butter, it is not the filthy story, but it is our thought of the hair of questionable origin, already being in our stomach, which makes one throw up that objectionable article by expressing the stomach contents for which one voluntarily, although almost unconsciously, uses the respective muscles. It is not the hair *per se* which makes that person vomit; it is a certain disgusting incident in which hair played a rôle. The sight of the hair in his food at once reminds the individual of such disgusting incident, and he, imagining the hair already in his stomach, voluntarily uses the necessary muscles for expressing the stomach contents. The act of vomiting has been produced by voluntary action of the muscles, not by reflexes.

Given an alimentary canal in which prevails the chemicopathological condition described by me as organacidia gastrica, in conjunction with a sudden jar to the inertia of the abdominal organs, as occurs to such organs in a sudden rise or sudden fall, as in the rolling of the ship, or in the sudden ascent and sudden descent in the elevators of our buildings, or in being violently thrown forward or backward when our electric cars suddenly stop or suddenly start, I can readily understand how the abdominal muscles just as suddenly and just as violently contract and protect the abdominal organs by thus contracting upon them, and this very violent contraction produces the vomiting. But I am not even willing to ascribe so much intelligence to the muscles. Whether suddenly rising or suddenly sinking, the abdominal organs, provided with considerable free motion, are thrown in the opposite direction by the physical, centrifugal force. This not only throws them against the abdominal muscles, which respond by contraction, but at the same time the hollow and highly elastic stomach and intestines are violently compressed, which again is the cause of the vomiting. Now, if a normal alimentary canal will require 100 units of force to produce such an effect, an affected alimentary canal might respond already to a force of but 50 units. I believe, in this

explanation we have something more concrete, something more substantial than the mysterious "reflex action." By the term of reflex action, as is commonly used in our science, we attempt to explain what we cannot otherwise explain. If we are to term every phenomenon of our life as due to reflex action, then, of course, all honor to reflex action. But the general profession does not take reflex action in that sense. With the same propriety we might call every chemical phenomenon—oxidation, ignition, explosion, etc.—a reflex action. Throw a little acid upon marble and marble shows evidence of irritation; it gets excited, begins to boil, gives off gases, etc. Are we not to understand by irritant as something abnormal to the body with which it chances to come in contact, abnormal either in quantity or quality, or in both?

Permit me again to assert that whenever vomiting occurs easily, the individual so vomiting must have his digestion inquired into, whether he as yet gives other symptoms or not. The cases in which the stomachs are profoundly affected and yet give no appreciable symptoms are many indeed. They go along heedless of slight digestive disturbances, believing themselves quite healthy until they suddenly collapse.

Concerning the green vomit I fear Dr. Benedict misquotes me. I do not believe ever having stated that green vomit was invariably due to green mold. I simply stated, and I do again repeat, that green vomit is most often due to mold, and I further state that the presence of bile can never be assumed, but must be proven by suitable means. I am glad that Dr. Benedict admits that he has also seen a few cases of green stomach contents in which the color was not due to bile, but to mold. And yet this seems not to have been known up to the time of my publication, and as to the respective frequency I do not wish to enter into any discussion, or controversy. I have also stated in some of my papers that I have always failed to get bile reactions while at the Augusta Hospital, Berlin; in Berlin, not in New York. That the green color of the stomach contents is not necessarily due to bile was also described by Dr. Kühne, an assistant of Professor Riegel of Giessen, Germany, some four months after my publication. Whether this work of Dr. Kühne was inspired by my publication I cannot say; Dr. Kühne does not say it either. But Professor Riegel received one of my reprints with a synopsis of it in German, much before his assistant's work was published. So, green stomach contents are not only not necessarily due to bile in New York, but neither in Berlin, nor in Giessen.

As to the decidedly yellow color (color of yolk of egg) of the aspirated stomach contents I fear Dr. Benedict may have to come to the same conclusion to which I recently came. And this is that such yellow contents do not come from the stomach but from beyond it, and that in such cases we deal with insufficiency of the pylorus. That the contents thus come from the intestines need not surprise us if they contain bile. I hope to speak on that at length at some future time.

Concerning appetite the old contention adhered to by Dr. Benedict does not work both ways. If appetite were simply the expression between cellular demands and nutritive supply, then we ought to assume that the absence of appetite means absence of any cellular demand for fresh nutritive supply. Does Dr. Benedict hold such view? How would Dr. Benedict explain the sudden appearance of appetite in some people immediately after drinking some cold water? Are we to assume that in the many patients with long standing anorexia there is no cellular demand for fresh nutritive supply? Does Dr. Benedict suppose that immediately after the introduction of the food into the stomach, when most usually hunger ceases, the cellular demand for nutritive supply has already been appeased, when it is well known to us that before the cells can derive their nutrition from the food just ingested, such food has yet to travel through quite a distance and be subjected to quite a good many and complicated chemical processes; that such travel and such chemical processes require a great deal of time, hours and hours; that long before the food has gone through its various digestive stages, long before such food had been finally absorbed and then distributed, we had already eaten once and again and were every time satiated after eating? No, no. Hunger is a lesser degree of pain, and is produced by the contraction of the muscular wall of the stomach, most likely, however, best appreciated by the pyloric region. We feel the hunger in the pit of the stomach. The stronger the contraction the more pronounced the appetite; the longer the contraction lasts, the longer lasts the sensation of hunger; the shorter is the duration of the contraction, the more evanescent is the hunger. Dr. Benedict seems to be somewhat confused about the area of the stomach, of which I mentioned nothing. A larger area of the stomach, surely, does not preclude its capability to contract. Contraction of the stomach means appetite, and, *vice versa*, relaxation and distension produce absence of appetite, anorexia.

In conclusion I wish to assure Dr. Benedict that I have taken his letter in a friendly spirit, and I hope that my answer will be likewise so received.

MARK I. KNAPP, M.D.
136 EAST SEVENTY-EIGHTH STREET.

## CIRCUMCISION IN INFANCY.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Inasmuch as the article on "Circumcision in Infancy," by Wm. B. Harlow, M.D., appearing in your issue of September 26, 1903, has been severely criticised by at least two writers, I beg space to indorse the article in question. I hardly think anyone, after a careful reading of article will maintain that the writer holds that cases never arise requiring circumcision. The purports of article seemed rather to call a halt on the all-too-frequent removal of a necessary covering of an important organ. If we remember that the foreskin is richly endowed with sebaceous glands, and especially about the duplicature where it becomes continuous with the closely adherent covering of the corona, we will be forced to admit that Nature has an object, and that object seems to be the protection of the delicate parts covered by this fold. The secretion by this delicate skin (not mucous membrane), of the smegma præputii is not an accident. but seemingly has a twofold porpose, viz., to lessen the friction of the folds and to prevent irritation from the presence in this field of abnormal urine. Now, if this be the correct view, the smegma is not the cause of irritation, but is rather an aid in preventing it, and in the large number of cases a careful examination of the urine will disclose the difficulty, and proper steps taken will correct the fault, and the smegma may remain to carry out its appointed work.

I agree with Dr. Shellenberger regarding the use of the probe to bfeak down adhesions. In fact, I believe the large majority of cases actually requiring something to be done, can best be treated by the probe, and thus we avoid the necessity of removing the foreskin. In regard to the question of self-abuse, the most inveterate case of the kind I ever had was in a boy upon whom circumcision had been done several years before. I think that this habit is not a question of prepuce or no prepuce but one of the environments of the particular case.

T. SHIELDS COLLINS, M.D.
BISBEE, ARIZ.

## Progress of Medical Science.

*The Boston Medical and Surgical Journal*, Nov. 5, 1903.

**Observations on the Iodine Reaction in Children.**—Charles Hunter Dunn gives a general summary of results from the cases in which he has observed the iodine reaction in children: (1) The reaction is always present, usually of average and often of marked intensity, a high percentage of cells being affected in the following conditions: Lobar pneumonia, bronchopneumonia, cerebrospinal meningitis, influenza, empyema, supuration (non-tuberculous), and was found present in single cases of appendicitis, diphtheria, and starvation. (2) The reaction is usually present, but may be absent, in cases of typhoid fever and miliary tuberculosis. (3) The reaction may be absent or present in anæmia. (4) The reaction is usually absent but may be present in nephritis, cardiac valvular disease, and tuberculosis.

**On Gastric Tetany.**—B. G. A. Moynihan declares that the records given by many writers show that gastric tetany is an extremely serious and often fatal disease. But nearly all of these serious cases cited by various authors are of old standing. For months, or for many years, the chronic gastric ulcer, the consequent stenosis, the dilated and hypertrophied stomach, have all caused trouble. Severe gastric tetany is seen only in the late stages of such cases. Such late stages are preventable. Three leading theories concerning the etiology of gastric tetany have been advanced. The first theory attributes this tetany to the general desiccation of the tissues of the body. The second theory suggests that the tetanic spasms are due to a reflex action aroused by the stimulation of the sensory nerves of the stomach. The third theory is that of autointoxication. In nearly all of the recorded cases of gastric tetany, dilatation of the stomach has been a pronounced feature. The medical treatment of gastric tetany consists in frequent and thorough lavage, strict dieting, and the administration during the height of an attack, of sedatives. By treating the cases of severe gastric tetany surgically, the lethal type of this disease will soon disappear. The earlier adoption of surgical measures in these gastric conditions in which there is grave mechanical impediment to the free working of the organ, will banish the last desperate forms of gastric tetany.

*Journal of the American Medical Association, Nov. 7, 1903.*

**Leprosy in the Hawaiian Islands.**—Judson Daland has made a study of this disease at the Molikai leper settlement, and states that the prevailing opinion in the islands concerning the disease is as follows: (1) The Bacillus lepra is the cause of this disease. (2) This disease is feebly contagious. (3) The Hawaiian is peculiarly susceptible to leprosy. (4) The Caucasian possesses a high degree of immunity. (5) Syphilis predisposes to leprosy. (6) Heredity is a factor of but little importance in the causation of this disease. (7) Segregation prevents the spread of leprosy. (8) The precise manner in which this disease is ordinarily transmitted from the sick to the well has not been proven. (9) There is no cure for leprosy. (10) Benefit may be derived from good hygiene, good food, climate, hot baths, and the antiseptic treatment of ulcerative surfaces.

**Leprosy from a Sanitary Standpoint.**—Isadore Dyer gives an historical summary of the spread of the disease, and has the following to offer concerning its prevention: First, as to the individual, either the patient should be segregated with those of like condition, or else, if he lives in his own family, he should be given a separate room; should have his meals alone; should wash his own utensils and should have his laundry boiled separately. The author believes that this is difficult, because, even when the family are aware of the disease they become careless in the family relations. Second, as to the public. The proper public care of lepers provides (*a*) segregation under systematic methods which should consider (1) the segregation of the sexes; (2) some arrangement by which the trophic or nerve type should be entirely separate from the tubercle type or skin leprosy, because there is no reason why a leper with nerve leprosy should not acquire fresh lesions from infection by a new contagium carrying the leper bacilli, found so freely in the tubercle type. Heretofore leprosy has been held as incurable, and the simple diagnosis of leprosy has been sufficient to condemn a victim, irrespective of the type, and he is doubly condemned if he is exposed to fresh infection while he is trying to get well. (*b*) Particular methods of sanitation should obtain. No institution pretending to care for lepers should be without the fullest equipment for bathing facilities, both medical and plain. Water in leprosy is as potent in its prophylaxis as it is for remedial use.

**A Case of Combined Diaphragmatic or "Bimanual Massage of the Heart" During Collapse Following Chloroform Narcosis.**—The patient of H. M. Cohen was a woman of thirty-two years operated on for ovarian cyst. The collapse from the anæsthetic came on fifteen minutes after the commencement of the operation. After the usual measures employed for two minutes had elapsed and no reaction had been established, he introduced his left hand into the abdominal cavity, pushed along the anterior abdominal wall until the diaphragm was reached, and, placing the hand, palm upward, in about the position the heart would normally be; that organ was easily grasped through the relaxed and intervening diaphragm. There was an entire absence of heart action. Placing the right hand over the præcordial region, externally, he plainly palpated the heart, as it lay between his two hands. In other words, with the heart grasped between the two hands he practised "bimanual palpation." He then began rhythmical compression of the heart, using both hands, at a rate of about sixty times a minute. After about thirty seconds a slight beat was felt by the left hand. The heart now began slowly to beat, gradually increasing both in strength and rapidity of beat, until at the end of one minute after massage began the beats registered about eighty per minute, and respiration began to be partially reëstablished. About two minutes after this respiration was normal, pulse 80 and, shock being apparently recovered from, the anæsthetic was changed to ether, and the operation finished in about thirty minutes. At the completion of the operation the patient was in good condition.

*Medical News, November 7, 1903.*

**Circular Laceration of the Cervix Uteri.**—Hugh Crouse declares that the porous cervix nearly always shows some signs of laceration. The degree varies from a mere indentation to a circular separation of the cervical tissue. The literature is very barren in regard to circular laceration. The writer reports two cases of this kind. In the first case a peculiar ribbon of tissue was united to the extent of half an inch at both ends, to the cervix. The condition was seen to be a circular laceration of the cervix. Ten hour had intervened since the delivery of a child by a midwife, and the parts between the attached ends were black and devitalized. The band was removed by means of scissors, the edges sterilized, and antiseptic douches ordered twice a day with good results. In the second case the posterior lip of the cervix was found to have a circular tear involving nearly half of the circumference, the breadth of separated tissue being about half an inch. Snug iodoform gauze packing was applied with good results.

**A Study of Immunity; Ehrlich's Side-chain Theory.**—F. M. Pottenger states that Ehrlich, while working to standardize diphtheria antitoxin, made several important observations which finally led to the enunciation of his side-chain theory. Among other important observations he noticed that toxin and antitoxin combine in definite proportions, that this combination is hastened by heat and retarded by cold, and that it takes place more quickly in a concentrated than in a weak solution. These facts showed this action between toxin and antitoxin to be very much like other chemical reactions. Ehrlich conceives of the body cells, the writer says, as consisting of a central nucleus and a number of side-chains or receptors. These side-chains possess certain affinities which are satisfied by, or correspond to, certain side-chains of cells, which are introduced from without the organism. These side-chains have to do normally with the nutrition of the organism, the food material being taken of by its combination with the side-chains of the cell. When a poisonous effect is produced upon the organism, it likewise must be produced by a combination being formed between it and some of these side-chains. It cannot be, the writer believes, that nature has endowed the cells of the organism with special side-chains for poisonous materials, but rather that these poisons are capable of forming unions with some of those which are normally intended to seize upon nourishing particles. When a poison has attached itself to a cell through its side-chains, if the action of the poison is slight, the cell is only slightly injured, and tends at once to reproduce the injured side-chains. It is likely that not only enough of these are produced to replace the injured ones, but also that a larger number are formed, which are cast off into the blood and lymph stream. They are the antitoxin. They combine with the poison and prevent it from combining with the side-chains which are still fastened to, and a part of the cell. Behring says: "The same substance which, when incorporated in the cells of the living body, is the prerequisite and condition for an intoxication and becomes the means of cure when it exists in the circulating blood."

*New York Medical Journal, November 7, 1903.*

**Deep Breathing.**—R. C. Newton offers the following conclusions: (1) Deep breathing is essential to good health, and is in many cases a valuable therapeutic measure. (2) Its importance is not at all generally appreciated. (3) It should be a part of every child's education. (4) It is especially indicated for backward and sickly children. (5) The profession owes it to itself to study more deeply this vital question and to be able to instruct the laity fully upon all its bearings.

**The Importance of the Physical Examination of the Abdomen as a Routine Practice, Irrespective of What Be the Symptoms.**—M. J. Knapp reports a series of cases illustrative of the fact expressed in the title of his paper. Thus, Case 1 complained of dyspepsia. Examination showed a displaced kidney. Case 2 was supposed to have a prolapsed uterus, but also had floating kidney. Case 3 had organic heart disease, but abdominal examination showed a tumor supposed to be of the omentum. Radiography showed it to be probably a stony tumor of the head of the pancreas. Case 4, diagnosticated as gastritis, had, as proven by operation, an adenocarcinoma of the pylorus. Case 5 complained of fulness in the abdomen and gnawing sensation before eating. Examination showed a gastric tumor. Case 6 complained of dyspepsia and cramps; was found to have an enlarged spleen adherent in the left iliac fossa. Case 7 had suffered from indigestion, but had a tumor of the jejunum.

**Some Principles on Which Is Based the Therapeutics of Electricity in Nervous Diseases.**—A. D. Rockwell believes that the reasons why so many physicians are disappointed in the results of electrical treatment are: (1) Ignorance of the physics and physiology of the method employed. (2) Imperfect technique. (3) Failure to appreciate the differential indications for the use of the various modalities. He then discusses the conditions presented by various common maladies so far as indications for the employment of electricity are concerned. Concerning true neuralgia he notes that pressure invariably increases the pain, while in pseudo-neuralgia it often affords relief. In these cases the local application of the cathode is to be preferred to that of the anode. Not only this, but the faradaic current itself is peculiarly effective in such cases, and will give relief when the galvanic utterly fails. But there is another reason, and one perhaps that will be more readily appreciated, why electricity relieves pain. It does it through its influence over vasomotor activity. All pain is necessarily due to nerve pressure, and

by exciting the activity of the circulation through congested areas—inducing, indeed, a sort of circulatory drainage—the disappearance of pain is often coincident with relief of pressure. It acts very much on the principle of the applicaion of heat, the difference being that its effects are more far-reaching, as evidenced, for example, by its influence over the pain of deep-seated malignant growths.

*American Medicine, November 7, 1903.*

**Nostalgia and Melancholia in the Tropics.**—E. S. Corson concludes: (1) That Americans, owing to their strenuous mode of living and the depressing conditions of the tropical climate, are especially liable to nostalgia and melancholia. (2) That persons suffering from nostalgia should be watched, and when it is complicated by melancholia they should be advised to return home at once. (3) That sanatoriums at high altitudes, if not already provided, should be exploited at once for the recruiting of the health of soldiers and civilians. Only the Government can do this. (4) That an especial effort should be made to educate all persons residing there as to the best methods of living for the preservation of health.

**Hyaline Bodies in Tumors and Other Kindred Conditions.**—Randle C. Rosenberger presents the following conclusions: It is seen from the specimens studied that these hyaline bodies were observed with great regularity. They were in most cases quite deeply situated in the tissues, while a great many more were seen intracellularly. Some of them gave quite a typical reaction of amyloid material, while the greater number failed to give this reaction, Treating them with dilute hydrochloric acid failed to produce effervescence. The writer believes that they correspond most closely to the fuchsin bodies described by Russell, and that they really represent some degenerative change occurring in the cell or cell nucleus. That they play some part in the etiology of the conditions in which they are found seems doubtful, notwithstanding the fact that they are found deeply situated and intracellular. They do not possess the peculiar intracellular characteristics which Plimmeis bodies do, being distinctly hyaline. They may, however, represent a hyaline or amyloid degeneration of blastomycetes. The fact that cultures were not obtainable in any case upon various media and the failure to demonstrate true budding seems almost positive proof. the writer believes, that they are not blastomycetes.

*The Lancet, October 31, 1903.*

**An Antenatal Case of Measles.**—J. R. Gibson reports the case of a woman attended in a third and normal confinement. The nurse when washing the child called attention to some dull red spots on the buttocks. A suspicion was entertained of a syphilide, but no opinion was expressed, as the two previous children were very healthy and the character of the parents was above reproach. On the next morning the uncertainty was cleared up, for the author found the child covered with a typical measles rash and suffering from suffusion of the eyes, nasal catarrh, and bronchitis, and, in short, all the cardinal symptoms of measles. The child recovered in the usual period and without any medicinal treatment. The temperature ranged from 99° to 100° F. The mother made an uninterrupted recovery and showed not a single symptom of measles. When the baby was eight months old the other two children took the measles but the baby did not. The mother had had measles when a child.

**On the Great Importance from the Point of View of Medical Science of the Proof that Bacteria and Their Allies Are Capable of Arising De Novo.**—H. Charlton Bastian calls attention to the important bearing of the possible origin of bacteria *de novo* on the theory of the origin of contagious disease. He notes that under the influence of unhealthy local or general conditions the common microorganisms entering the body may possible be made to take on new properties and be, in fact, converted into one or other of the so-called specific or pathogenic organisms. Certain experiments on the lower animals seem to show that certain germ-free chemical substances can set up a septicæmia indistinguishable from that set up by bacteria. Frequent epidemics of typhoid fever have occurred in which it has been assumed that the disease has arisen *de novo*, The results of treating tuberculosis in modern sanatoria seem to the author to favor the view that it is commonly an affection produced *de novo*, and altogether apart from contagion. What the author has to say with regard to tuberculosis, he regards as equally applicable to leprosy, with perhaps certain slight variations. It cannot be denied that the disease is to a slight extent contagious, but there is much evidence to show that in the main it arises *de novo* There is certainly nothing unreasonable in the supposition that putrid fish, or other bad food of like kind. may carry into the system bacteria and the toxic products which they have formed, and that the continued influence of such bodies may in some persons act as irritants, and either engender or awaken organisms in this or that tissue having the characteristics of the leprosy bacillus, just as boiled dilute liquor ammoniæ injected into the subcutaneous tissue of a guinea-pig or a rabbit produces, even within a few hours, swarms of the bacillus met with in "Pasteur's septicæmia," so called, or as two or three drops of putrid blood in the same situation may give rise to the appearance throughout the body of swarms of the more distinctly specific bacilli which suffice for the indefinite propagation of what is known as "Davaine's septicæmia."

*British Medical Journal, October 31, 1903.*

**Two Cases of Epithelioma of the Larynx Remaining Well Two Years after Operation (Thyrotomy).**—Eugene S. Yonge reports these cases: The first case was that of a man aged fifty-seven years. His first symptom was hoarseness. This had lasted for about twelve months when he presented himself for examination. The second case was that of a man aged sixty-seven years. He had been hoarse for eighteen months. In both instances tracheotomy and thyrotomy were performed. The results so far are excellent, as in each case the voice is useful, and as yet there has been no recurrence, two years after operation.

**The Surgical Treatment of Cancer of the Larynx.**—E. J. Moure discusses first the treatment of extrinsic cancer of the larynx. In the case of a very limited growth which has begun near the free edge of the epiglottis, on its lingual and laryngeal surface, its removal may be accomplished by the snare or cutting forceps. When the growth is more extensive, it becomes necessary to perform an external operation. For this purpose the writer prefers transhyoid pharyngotomy. In cases of intrinsic cancer of the larynx thyrotomy has been reinstated in favor. If during the operation of thyrotomy malignant degeneration of part of the thyroid cartilage is observed, partial laryngectomy may be indicated. If the growth is still more extensive, the whole larynx may be removed. The writer insists upon the supreme importance of early diagnosis.

**A Discussion on the Operative Treatment of Malignant Diseases of the Larynx.**—Felix Semon states that the history of radical operations for malignant disease of the larynx is of comparatively recent origin. He reviews briefly the various forms of operation. There is first of all the intralaryngeal method, which, according to the writer's belief, is well adapted to the removal of growths from the surface of the laryngeal tissues. But a characteristic of malignant neoplasms is their infiltration of the mother soil. In such cases this method is not a satisfactory one. The operation of thyrotomy is indicated in all cases of intrinsic malignant diseases of the larynx, in which the diagnosis is made at a time when the disease is not too extensive, nor apparently too deeply infiltrating. Partial extirpation of the larynx is next considered. The writer believes that the earlier the diagnosis is made, the rarer this operation will become. There are certain cases in which the performance of total extirpation of the larynx may become unavoidable to save the patient's life. Subhyoid pharyngotomy is suitable for cases in which the disease starts from the epiglottis, or from the aryteno-epiglottidean fold. Its technique is easy, and it offers a good view of the field of operation. The writer finally discusses palliative tracheotomy. He believes that operative treatment of malignant disease of the larynx will yield the more satisfactory results, the sooner the diagnosis is made, and the earlier and the more thoroughly operation is carried out.

*Deutsche medinische Wochenschrift, October 22, 1903.*

**The Mechanism of Intestinal Strangulation.**—Wilms reiterates his previous conclusions regarding the mechanical components of the force which causes internal strangulations to increase in volume at the expense of the emerging loop. Kertecz has assailed these mainly on the strength of experiments conducted on the rabbit, but the author considers that the comparatively weak peristalsis of this animal's intestine does not permit the assumption that human gut will behave in an analogous manner, and also that Kertecz's investigations were carried on mainly under conditions similar to those prevailing in strangulated external hernias, and not comparable to those existing ininternal strangulations in which an equal pressure is exerted both on the strangulated and non-strangulated gut. Kertecz believes that peristalsis is wholly inactive in the increase in size of the strangulated portion, while intra-abdominal pressure supplies most of the force, and that it is the emerging loop which is pushed through the constricting ring, owing to the greater distention of the entering loop. The author's view is that the emerging loop

is drawn through the ring first by peristalsis and, secondly, if the constriction is so tight as to check this, by the distention of the incarcerated gut. It is the emerging loop which is drawn in under the latter conditions, owing to the fact that the entering loop is usually more firmly adherent to the constricting ring.

**The Etiology of So-called Rheumatic Tetanus.**—Racine and Bruns report a case which confirms the view that idiopathic and rheumatic tetanus do not exist. If a thorough search does not reveal the site of entry of the infection the disease may be called cryptogenetic, but not idiopathic. In this case the patient a miner, reached the hospital, presenting the typical picture of tetanus, after five days of symptoms gradually increasing in severity. Under serum therapy he improved and was discharged, cured on the nineteenth day. Not the slightest abrasion could be found about the nose or throat, or on the surface of the entire body, and there was no history of any injury. The case therefore fitted exactly the ordinary description of "idiopathic" tetanus, but on the third day of his hospital treatment the patient admitted having suffered about three weeks previously from a discharge from one ear. To relieve the irritation caused by this he attempted to clear the meatus with straws torn from the broom with which he was accustomed to sweep the floor of the mine, and which was necessarily soiled with horse dung. Cultures made from the cerumen of the ear gave positive results, and the mystery was solved. The authors, therefore, advise most caution before making the diagnosis of idiopathic tetanus, and recommend that aural examination be added to the routine in all such cases.

*Münchener medicinische Wochenschrift, October* 20, 1903.

**Toxin and Antitoxin.**—Gruber belabors sharply Ehrlich's doctrines concerning the relations of toxins and antitoxins and characterizes them as speculative vagaries without a basis in fact. He believes that Ehrlich's attempts to reduce the changes taking place in living tissues to chemical reactions do not offer any hope of success and brings forward various general statements to prove the fallacy of Ehrlich's theories. His own idea is that the formation of antibodies is of the nature of a secretory activity resulting from long-continued stimulation, a process therefore likely to remain incomprehensible indefinitely.

**A Mirror Sphygmograph.**—Frank describes an important improvement in the construction of sphygmographs intended to obviate the errors due to the mechanical faults of the instruments now in common use. These all depend on a series of levers to convey a record of the excursions of the arterial wall to a strip of smoked paper. Two sources of error enter into such a mechanism, the inertia of the masses involved and the friction of the numerous moving parts. The author employs a pad brought into contact with the vessel by the usual means, but actuating instead of the customary system of levers, tambours, etc., simply a mirror which reflects a pencil of light into a moving photographic film, and thus leaves a record of its oscillations. By the use of the modern daylight loading film cartridges and developing machines the process becomes very simple in its execution and the apparatus is sufficiently compact and easy of manipulation to permit of bedside observations. Owing to the strong illumination employed to furnish the ray of light the observations do not require to be made in a dark room.

*Journal of Tropical Medicine, October* 15, 1903.

**Notes on the Culicidæ of Dehra Dun.**—F. Wyville Thomson describes a new mansonia with spotted wings, which closely simulates the anopheles. He complains of the ignorance and apathy of the laity in the Himalayan foothills, who still breed domestic mosquitos by the millions, no amount of advice inducing them to take the trouble of going around to empty or oil their tanks, etc. With regard to oiling, the author has found that a mixture of a little ghi with kerosene seems to spread better, the pure oil remaining in globules unless agitated. Ghi shoots out over the pool quickly, or makes the oil do so.

**Remarks on the Panama Canal, and the Introduction of Yellow Fever into Asia.**—St. George Gray states that his attention has been called to the fact that in a previous article he omitted to point out that steamers may serve as breeding places for mosquitos and thus carry infection to other countries. The omission was due to an oversight. In regard to the question of whether the organism of yellow fever can be transmitted by the female imago to her offspring, he says that it appears unlikely. His previous suggestions were not meant as a fixed guide for the prevention of yellow fever, from which there could be no deviation, but merely an outline of precautions to be taken. Nothing should be left undone that will aid in keeping the scourge of yellow fever from the densely crowded cities of the East.

**Note on the Use of Kerosene as a Culicicide.**—St. George Gray, from his experimentation, concludes that when ordinary illuminating oil is used as a larvicide, *all* the adult insects that come to oviposit are not killed by it, but that the majority of the mosquitos get away after laying their eggs. Of course, the larvæ never develop under the film of oil. There is, however, no better larvicide than kerosene, and the author uses it freely to keep down the number of mosquitos, but he wishes to emphasize the point that it does not kill all the adult insects that come to lay their eggs on the surface of the water. Crude petroleum would probably have killed more of the insects.

**Varioloid Varicella in Trinidad.**—J. R. Dickson says that this disease was at first considered to be varicella. It is a febrile disease contagious in nature, with definite stages of incubation, invasion and the appearance of a cutaneous eruption. The incubation period is from ten to fifteen days, the invasion about three days, with headache, muscular pains, and fever. The rash usually appears on the fourth day as papules, going through the successive stages of vesiculation, suppuration, desiccation, and desquamation. It invades the body in successive crops. The extremities, face and back of the trunk are the parts most affected, the palms of the hands and soles of the feet were frequently affected. The severer the case the more copious relatively is the rash on the trunk, and the elements show a greater tendency to be confluent on the forearms and flanks than on any other part of the body. The mortality is very low—about 0.44 per cent. The outstanding feature of the disease is its atypical character. In upward of 95 per cent. of the cases there is no fever after the period of invasion.

**The Treatment of Traumatic Articular Affections.**—M. Mally and M. Richon conclude that in all functional impotence following articular traumatism we should always bear in mind the spinal affection closely connected with articular disease, whose best known and most evident symptom is reflex amyotrophia. Clinically this will be manifested by an exaggeration of the excitability of the muscle and of the tender reflexes, and by the appearance of spasms, and painful contracture. If spasm be absent, the joints may be treated by mobilization and massage, and the muscles by electricity, If there be spasm, faradization and massage must be proscribed, and electricity applied in sedative form. Even in cases of incurable reflex amyotrophia, static electricity will be of benefit in overcoming pain and calming spasm.—*Archives Générales de Médecine*, September 29, 1903.

**Sweating in Pulmonary Tuberculosis.**—V. E. Bouic holds that the sweating in tuberculosis is due to the direct action of the Koch bacillus and its toxins, in addition to other toxins of the body. Sweating, fever, emaciation, digestive troubles, etc., are all due to the same cause, *i.e.* the infection of the organism. The perspiration plays a useful part in moderating the fever by evaporation, and in eliminating a certain amount of toxin, but it causes insomnia, induces chilling and weakens the patient. It must be treated (but not suppressed) by treating the cause—in other words, the intoxication. The kidneys should be acted on by milk, and various diuretics; the bowels left open by enemata, laxatives, and purgatives if necessary. Should this treatment be of no avail, the sweating should be left to do its work of elimination.—*Gazette des Hôpitaux*, September 29, 1903.

**The Nasal Treatment of Dysmenorrhœa.**—Aristide Malherbe says that Thiers of Berlin has demonstrated that many disorders of menstruation are directly traceable to disturbances in the nasal fossæ. The statement when first made was received with incredulity, but Schiff corroborated it later, and the present writer has carried out researched in the same line. The anterior extremity of the inferior turbinated bone and the "tubercle" of the septum are often the seat of decided congestion during menstruation, bleeding readily and being extremely sensitive to the touch. The author holds that the reflex genital pains are due to some special condition of the innervation of the nasal mucous membrane, and perhaps to some alteration of the mucous membrane of these two spots in the nose. The treatment which he adopts, and which has in thirty-five cases yielded absolutely satisfactory results, is the insertion of tampon impregnated with a 5 per cent. cocaine solution, followed by cauterization with the galvanocautery. This is done in the interval of the menses, and may have to be repeated once or twice. In the case of hypertrophied mucosa, the latter may be removed under ether, being careful not to injure the cartilage. Much temporary relief of pain may be given, at the time of menstruation, by the application of cocaine tampons to the so-called "genital points" of the nose, referred to above.—*Le Bulletin Médical*, October 21, 1903.

A Textbook of Clinical Anatomy for Students and Practitioners. By Daniel E. Eisendrath, A.B., M.D., Professor of Clinical Anatomy in the Medical Department of the University of Illinois, Attending Surgeon to the Cook County Hospital, Chicago. Philadelphia, New York, and London: W. B. Saunders & Co., 1903.

The novel title of this work is in keeping with its subject. The term Clinical Anatomy may be understood as anatomical knowledge applied to clinical work. The importance of such a study must be admitted by all, and the thoroughly practical manner in which the author has performed his task will meet with general approbation. It is applied and topographical anatomy in its larger and more direct sense as the essential aid to the correct interpretation of morbid phenomena. The author rightly says that the ordinary student in his dissections is mostly contented to memorize relations rather than make them useful object-lessons. Hence in his after-work he is often at a loss to locate accurately organs and properly appreciate topographical relations. Even the operating surgeon who is supposed to be most accurate in his anatomy is often amiss in his landmarks and needs a constant reminder of important relations. In the laudable endeavor to supply this lack of knowledge the author has by numerous or schematic illustrations succeeded in representing various parts of the body in an apparently transparent condition, showing the proper relations of the deeper with the more external parts. A special recommendation for the figures is that they are mostly original and were made for the purpose in view, many of the surface outlines having been marked upon an artist's model and then photographed. The sections of joints and trunks are those of formalinized cavaders and are unimpeachable in accuracy. It is safe to say that both the medical and surgical clinician will find this work of inestimable value.

A Manual of Operative Surgery. By Sir Frederick Treves, Bart., K.C.V.O., C.D., LL.D., F.R.C.S. New Edition, revised by the author, and Jonathan Hutchinson, Jr., F.R.C.S., surgeon to London Hospital. Vol. I, 8vo, pp. 750. Philadelphia and New York: Lea Brothers & Co.

Only two years have elapsed since the first edition of this work appeared, and much revision has been required to keep up with advancing surgery during that period. The general plan of the manual remains, however, unaltered. The distinguishing feature of the work is the thoroughly practical one of definite modes of procedure in given cases as the outcome of individual experience. The practice is that of Sir Frederic, and represents the advanced school of English surgery. The lucid descriptions of operations appeal as directly to the inexperience of the beginner as to the convictions of the veteran. Many new illustrations have been inserted, adding materially to the general usefulness of the work.

An American Textbook of Surgery for Practitioners and Students. Edited by William W. Keen, M.D., LL.D., F.R.C.S. (Hon), and J. William White, M.D., Ph.D. Fourth Edition, 8vo, pp. 1333. Philadelphia, New York, and London: W. B. Saunders Co., 1903.

The present edition of this work shows evidences of much revision and elaboration in the chapters on Bacteriology, Tumors, the Osseous System, and the Surgery of the Joints, Nerves, Head, and Abdomen. The notable additions comprise the treatment of facial paralysis by anastomosis, the latest views on shock, goiter, hernia, aneurysm, the use of paraffin in nasal deformities, the various improved methods of spinal anæsthesia, and the new anæsthetics.

Six new chapters appear, adding nearly a hundred pages to the volume. These are on Military and Naval Surgery, Tropical Surgery, Examination of the Blood and Immunity. It is essentially an American work—all of the contributors being well-known American surgeons, and, of course, does infinite credit to the conception of its editors.

Modern Microscopy, a Handbook for Beginners and Students. By M. I. Cross and M. J. Cole. Third Edition. Chicago: W. T. Keener & Co., 1903.
